(12)

The plight of today's teenager in these socially turbulent times is often precarious at best. According to a recent national survey, there has been a 30% increase in teenage sexual activity in the last five years.[1] Also, half of all out-of-wedlock births are attributed to teens. Up to two-thirds of these are unwanted, unplanned births.[2] Trapped in the midst of rapidly changing sexual mores, the teenager is further beset by uncertainty, timidity, ignorance, and misinformation.

That's why today's younger patient needs and deserves thorough counseling — underlined by compassion, reassurance, and trust — in many areas. These range from the basic facts of life, in some cases, to more serious subjects like venereal disease. But, no issue is more sensitive, or more in need of physician/patient exploration than that of contraception.

Today, contraceptive counseling often culminates in the selection of a low-dose oral contraceptive like Brevicon. Brevicon offers a rate of efficacy comparable to higher-dose formulations and its incidence of menstrual irregularities is low. In 16,345 cycles among 1,168 patients, there were 0.22 pregnancies per 100 woman years. Breakthrough bleeding occurred in 5.1% of cycles, and amenorrhea in 1.0% of cycles. Dropout rate due to menstrual irregularities during the crucial first three months was 3.4%.

Counseling, compassion, and Brevicon — a good combination for many of today's teenage patients.

Brevicon® tablets **A sign of the times**

(norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)

1. Zelnik, M. and Kantner, R.: Sexual and Contraceptive Experience of Young Married Women in the United States, 1976 and 1971. Family Planning Perspectives. Vol. 9, No. 2, March/April 1977.

2. Monthly Vital Statistics Report: Natality Statistics, National Center for Health Statistics, Vol. 26, No. 5, September 1977.

Note: Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be fully aware of the prescribing information for this product.

Please see following page for summary of prescribing information.

(norethindrone 0.5 mg. with ethinyl estradiol 0.035 mg.)

Brevicon® 28-Day Tablets
(21 norethindrone 0.5 mg. with ethinyl estradiol 0.035 mg. tablets followed by 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

INDICATIONS O.C.s are indicated for the prevention of pregnancy. The drop-out rate for medical reasons, as observed in the clinical trials conducted with BREVICON, appears to be somewhat higher than observed with higher dose combination products. The dropout rate due to menstrual disorders and irregularities was also somewhat higher, dropouts being equally split between menstrual disorders and irregularities and other medical reasons attributable to the drug. *DOSE-RELATED RISK OF THROMBOEMBOLISM FROM O.C.s.* Studies have shown a positive association between the dose of estrogens in O.C.s and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The O.C. product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of O.C.s should be started on preparations containing 0.05 mg or less of estrogen.

CONTRAINDICATIONS 1. Known or suspected pregnancy (see Warning No. 5). 2. O.C.s should not be used in women who have or have had any of the following conditions: a. Thrombophlebitis or thromboembolic disorders. b. Cerebral vascular or coronary artery disease. c. Markedly impaired liver function. d. Known or suspected carcinoma of the breast. e. Known or suspected estrogen dependent neoplasia. f. Undiagnosed abnormal genital bleeding.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from O.C. use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use O.C.s should be strongly advised not to smoke.

The use of O.C.s is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing O.C.s should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of O.C.s is well established. One British study demonstrated an increased relative risk for fatal venous thromboembolism; two British and three American studies demonstrated an increased relative risk for non-fatal venous thromboembolism. These studies estimate that users of O.C.s are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke, which had not been shown in prior British studies. In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the relative risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers. A British long-term, follow-up study reported in 1976 a highly significant association between O.C. use and stroke. Another British long-term, follow-up study had suggested such an association in 1974, but the number of cases was too small to estimate the risk. MYOCARDIAL INFARCTION. An increased relative risk of myocardial infarction associated with the use of O.C.s has been reported, confirming a previously suspected association. One study conducted in the United Kingdom found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an O.C. user or not. O.C.s, however, were found to be an additional risk factor. In terms of relative risk, it has been estimated that O.C. users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. O.C. users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, and about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the number of cigarettes smoked is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. (The estimates are based on British vital statistics which show acute myocardial infarction death rates 2- to 3-times less than in the U.S. for women in these age groups; consequently, actual U.S. death rates could be higher.) The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in O.C.s. Preparations containing 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been supported by a study in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only O.C.s have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASE. A large British prospective study estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of O.C.s according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for O.C. users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000). The risk is concentrated in older women, in those with a long duration of use, and in cigarette smokers, and may persist after discontinuation of O.C. use. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of O.C.s) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The findings of this analysis are shown in Table 1 below. The study concluded that the mortality associated with all methods of birth control is low and below that of childbirth, with the exception of O.C.s in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates given would be about double; for "light" smokers (less than 15 cigarettes a day), about 50 percent.) The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The study also concluded that O.C. users who smoke, especially those over the age of 30, have a greater mortality risk than O.C. users who do not smoke.

TABLE 1. *The annual number of deaths associated with control of fertility and no control per 100,000 nonsterile women by regimen of control and age of women are:*

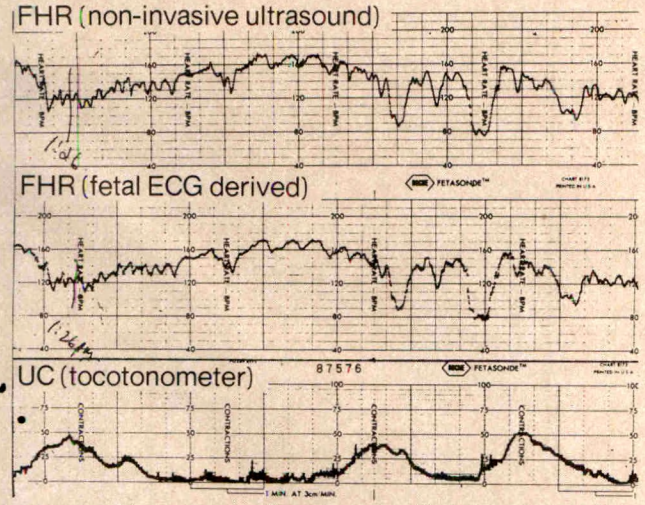
	15-19	20-24	25-29	30-34	35-39	40-44
No method	5.6	6.1	7.4	13.9	20.8	22.6
Abortion only	1.2	1.6	1.8	1.7	1.9	1.2
Pill only—nonsmokers	1.3	1.4	1.4	2.2	4.5	7.1
Pill only—smokers	1.5	1.6	1.6	10.8	13.4	58.9
IUDs only	0.9	1.0	1.2	1.4	2.0	1.9
Traditional contraception only	1.1	1.6	2.0	3.6	5.0	4.2
Traditional contraception and abortion	0.2	0.2	0.3	0.3	0.3	0.2

The risk of thromboembolic and thrombotic disease associated with O.C.s is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclampic toxemia and especially by cigarette smoking. Based on the data currently available, the following table gives a gross estimate of the risk of death from circulatory disorders associated with the use of O.C.s:

TABLE 2. *Smoking habits and other predisposing conditions – risk associated with use of O.C.s*

	Age	Below 30	30-39	40+
Heavy smokers		C	B	A
Light smokers		D	C	B
Nonsmokers (No predisposing conditions)		D	C,D	C
Nonsmokers (other predisposing conditions)		C	C,B	B,A

A—Use associated with very high risk. C—Use associated with moderate risk.
B—Use associated with high risk. D—Use associated with low risk.



The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of post-surgery thromboembolic complications has been reported in O.C. users. If feasible, O.C.s should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. Among patients with thromboembolic disease, the results of retrospective studies suggest the possibility of an increased risk for users who are of blood types A, B, or AB, as compared with those of type O. *Ocular Lesions:* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of O.C.s. Discontinue O.C. medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of certain adenomas, benign or malignant, such as those of the breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently contained in O.C.s, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies have reported an increased relative risk (3.1 to 13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women who took estrogen replacement medication to relieve menopausal symptoms. One publication reported on the first 30 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on O.C s. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time O.C.s were first given, polycystic ovaries) nearly all occurred in women who had used a sequential O.C. These products are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only O.C.s, although individual cases have been reported. Several studies have shown no increased risk of breast cancer to women taking O.C.s or estrogens. In one study, however, while no overall increased risk of breast cancer was noted in women treated with O.C.s, a greater risk was suggested for the subgroups of O.C. users with documented benign breast disease and for long-term (2-4 years) users. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. A reduced occurrence of benign breast tumors in users of O.C.s has been well documented. In a prospective study of women with cervical dysplasia, there was an increase in severity and of conversion to cancer *in situ* in O.C. users compared with nonusers. This became statistically significant after 3 to 4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to be predictive of progression after prolonged exposure. There have been other reports of microglandular hyperplasia of the cervix in users of O.C.s. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with O.C.s. Close clinical surveillance of all women taking O.C.s is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use O.C.s instead of other methods of contraception. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with O.C. use. This has been reported in short-term as well as long-term users of O.C.s. One study showed that O.C. formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Two studies relate risk with duration of use, the risk being much greater after 4 or more years of use. Although it is an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may clearly show a focal defect. Hepatic arteriography may be a useful procedure in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that O.C.s further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use O.C.s instead of other methods of contraception. Furthermore, a high percentage of women exposed to diethylstilbestrol (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported following use of sex hormones, including O.C.s, in pregnancy. In one case-control study it was estimated that there was a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (O.C.s, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including O.C.s, during early pregnancy occurred at a rate of 18.2 per 1,000 births, compared to 7.8 per 1,000 for children not so exposed *in utero*. These results are statistically significant. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing O.C.s. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping O.C.s is unknown. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if progestogen-only O.C.s are used) and further use of O.C.s should be withheld until pregnancy has been ruled out. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue O.C.s with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recom-

combinations to induce withdrawal bleeding should not be used as a test o pregnancy. 6. *Gall Bladder Disease:* Studies found an increased risk of ga bladder disease in users of O.C.s or estrogens. In one study, an increase risk appeared after 2 years of use and doubled after 4 or 5 years of use. I another study an increased risk was apparent between 6 and 12 months o use. 7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose to erance has been observed in a significant percentage of patients on O.C.s For this reason, prediabetic and diabetic patients should be carefully ob served while receiving O.C.s. An increase in triglycerides and total phos pholipids has been observed in patients receiving O.C.s. The clinical signifi cance of this finding is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with O.C. use. In some women, hyperten sion may occur within a few months of beginning O.C. use. In the first year o use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in O.C. users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, a history of toxemia or elevated blood pressure during preg nancy, a familial tendency to hypertension or its consequences, or a history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevation of blood pressure when given O.C.s and therefore, should be monitored closely. Even though elevated blood pressur may remain within the "normal" range, the clinical implications of elevatio should not be ignored and close surveillance is indicated, particularly f women with other risk factors for cardiovascular disease or stroke. Hig blood pressure may or may not persist after discontinuation of the O.C. 9 *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discon tinuation of O.C.s and evaluation of the cause. 10. *Bleeding Irregularities.* Breakthrough bleeding, spotting, and missed menses are frequent reasons for patients discontinuing O.C.s. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an O.C. with a higher estro gen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of throm boembolic disease. Women with a past history of oligomenorrhea or secon dary amenorrhea or young women without regular cycles may have a tend ency to remain anovulatory or to become amenorrheic after discontinuation of O.C.s. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumo (e.g., adenomas) has been associated with amenorrhea in former user compared with nonusers. One study reported a 16-fold increased prevalenc of pituitary prolactin-secreting tumors among patients with postpil amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing O.C.s in comparison with those discontinuing other methods of contraception. The impairment appears to be independent of the duration of use of the preparations. While the in pairment diminishes with time, there is still an appreciable difference in th results in nulliparous women for the O.C. and non-O.C. groups 30 month after discontinuation of birth control. For parous women the difference is no longer apparent 30 months after cessation of contraception. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contracep tive failures. However, in progestogen-only O.C. failures, the ratio of ectopic to intrauterine pregnancies is higher than in women who are not receiving O.C.s, since the drugs are more effective in preventing intrauterine than ec topic pregnancies. 13. *Breast Feeding:* O.C.s given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in O.C.s has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast fed child have not been determined. If feasible, the use of O.C.s should be deferred until the infant has been weaned. **PRECAUTIONS** *GENERAL* 1. A complete medical and family history should be taken prior to the initiation of O.C.s. The pretreatment and periodic physical examinations should include special reference to blood pressure breasts, abdomen and pelvic organs, including Papanicolaou smear and re vant laboratory tests. As a general rule, O.C.s should not be prescribed fo longer than 1 year without another physical examination being performed. Under the influence of estrogen-progestogen preparations, preexistin uterine leiomyomata may increase in size. 3. Patients with a history psychic depression should be carefully observed and the drug discontinued depression recurs to a serious degree. Patients becoming significantly de pressed while taking O.C.s should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. 4. O.C.s may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving O.C. therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. O.C. users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is unknown. 8. Serum folate levels may be depressed by O.C. therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping O.C.s, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of O.C. therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing O.C.s. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. *DRUG INTERACTIONS* O.C.s may be rendered less effective by virtue of drug interaction with rifampin, isoniazid, ampicillin, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers and antimigraine preparations. O.C.s may alter the effectiveness of other types of drugs, such as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., quanethidine), vitamins and hypoglycemic agents. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **ADVERSE REACTIONS** An increased risk of the following serious adverse reactions has been associated with the use of O.C.s (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving O.C.s and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, change in corneal curvature (steepening) change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution in lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors. The following adverse reactions have been reported in users of O.C.s, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function. **INFORMATION FOR THE PATIENT** (See Patient Package Insert)

Compare your invasive fetal heart rate recording with Roche Fetasonde® recording

We did! Roche indirect fetal heart rate recording can be as good as a standard invasive fetal heart rate recording. This will allow you to monitor most of your patients non-invasively most of the time. Don't be limited to a monitor that does not have that capability when a viable alternative is available.

The Roche 2106 Fetal Monitor is proven useful in virtually all antepartum patients:

- Accuracy approaching internal monitoring.
- Beat-to-beat heart rate variability.
- Complete internal monitoring capability—the 2106 can be used for all patients all the time.

The non-invasive fetal monitor Roche Fetasonde®

Vol. 134, No. 1, May 1, 1979. The American Journal of Obstetrics and Gynecology is published semimonthly by The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141.

Annual subscription rates.	*U. S.*	*All Foreign Countries*
Institutional*	$47.00	$64.00
Personal†	$32.00	$49.00
Student, resident†	$25.60	$42.60

Single copies are $4.50 postpaid. Remittances should be made by check, draft, or post office or express money order, payable to this Journal.

*Institutional (multiple-reader) subscriptions are available to public and private libraries, schools, hospitals, and clinics; city, county, state, provincial, and national government bureaus and departments; and all commercial and private institutions and organizations.

†Personal subscriptions and all student-rate subscriptions must be in the names of, billed to, and paid by individuals. All student-rate requests must indicate training status and name of institution.

Subscriptions may begin at any time.

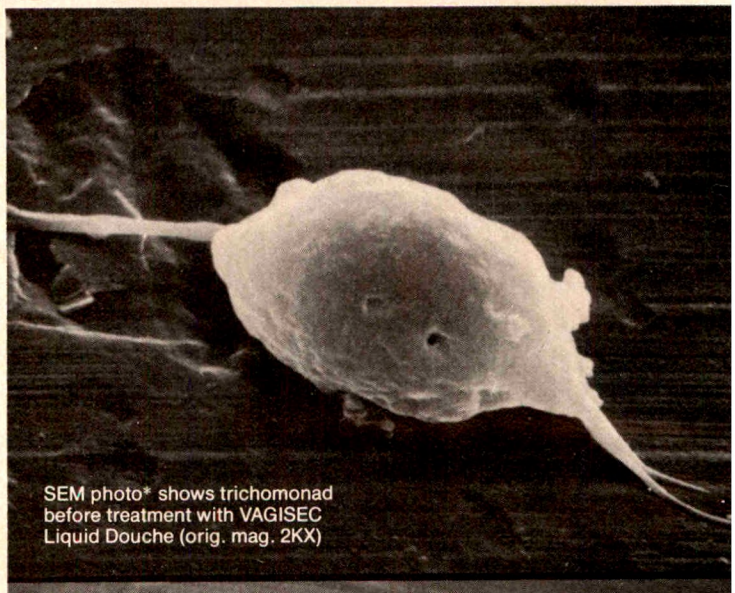
Second-class postage paid at St. Louis, Missouri, and additional mailing offices. Printed in the U.S.A. Copyright © 1979 by The C. V. Mosby Company.

The appearance of a code at the bottom of the first page of an original article in this JOURNAL indicates the copyright owner's consent that copies of the article may be made for personal or internal use, or for the personal or internal use of specific clients. This consent is given on the condition, however, that the copier pay the stated per copy fee through the Copyright Clearance Center, Inc., P.O. Box 765, Schenectady, N. This consent does not extend to other kinds of copying, such as copying for general distribution, for advertising or promotional purposes, for creating new collective works, or for resale.

Destroys Trichomonads in 15 seconds

Immediate symptomatic relief

In vitro studies[1,2] show that within 15 seconds of contact, VAGISEC Douche permeates the trichomonad's outer membrane and weakens its cell wall, causing it to swell and die.



VAGISEC Douche/ VAGISEC PLUS Suppositories

regimen for the treatment of trichomoniasis... or mixed vaginal infections

VAGISEC Douche acts on the trichomonads directly—far faster than most systemic medication. It penetrates the vaginal creases and folds; cleanses and dissolves mucinous material; and prevents buildup of microorganisms. Relief from itching, burning, leukorrhea and malodor is almost immediate.

VAGISEC PLUS Suppositories combines the same proved trichomonacide with effective antibacterial action against susceptible strains of staph, strep and coliform organisms,[3] and is particularly useful in mixed infections.

The combination douche/suppositories regimen is recommended in all cases, except during pregnancy, when douching is not recommended. Strict adherence to the treatment program is essential for therapeutic success.

SEM photo* shows trichomonad before treatment with VAGISEC Liquid Douche (orig. mag. 2KX)

15 seconds after treatment, photo shows cell wall destruction and loss of flagella (orig. mag. 5KX)

VAGISEC Liquid Douche/VAGISEC PLUS Suppositories
Contraindications: Douching is not recommended during pregnancy. VAGISEC Liquid Douche and VAGISEC PLUS Suppositories are spermicidal and should not be used on days when the patient is trying to conceive. **Precautions:** *Therapeutic Treatment:* Recurrence of vaginitis often indicates extravaginal foci or infection in cervical, vestibular and urethral glands, etc., or reinfection by the sexual partner. During treatment, patient should refrain from intercourse or the partner should wear a prophylactic. To prevent flare-ups after completion of therapy and for continued vaginal cleanliness, the patient is advised to continue with VAGISEC Liquid as a regular douche, but no more than twice weekly unless otherwise directed by physician. **Side Effects:** No significant side effects reported to date. Any minor irritation is alleviated by discontinuance of douche for a single day. **Administration and Dosage:** *Office Treatment (Adult):* For the treatment of vaginal trichomoniasis and mixed vaginal infections, best results are obtained by scrubbing the vagina with VAGISEC Liquid, diluted 1:100, by the physician in the office; 3 scrubs the first week, 2 the second. A suppository is inserted after each office scrub in the Liquid/Suppository regimen. Patient should be instructed to continue treatment at home. *Home Treatment:* Liquid/Suppository regimen: In all instances, the combination douche and suppositories are recommended for home use. The usual home treatment is VAGISEC Liquid Douche in the morning, followed by a VAGISEC PLUS Suppository inserted deep in the vagina and a second suppository inserted in like manner at bedtime, daily, for a period of 14 days. For those physicians who feel it important to treat the patient through the complete menstrual cycle, the Liquid/Suppository regimen may be continued throughout the month. It is advisable to continue treatment through two menstrual periods. Treatment should be omitted the night and morning preceding an office visit. Patients should be reexamined 3 days after home treatment has been discontinued. The full course of therapy must be completed to eliminate the infecting microorganisms from the vagina. In chronic or stubborn cases, therapy may be repeated with no interval between courses. During treatment, patient should refrain from intercourse, or the partner should wear a prophylactic. No patient should be considered cured until vaginal smears or cultures, taken at monthly intervals for 3 months following treatment, show absence of trichomonads and a return to the normal vaginal flora. **How Supplied:** VAGISEC Liquid—4 oz. plastic bottle. VAGISEC PLUS Suppositories—box of 28 3-gram suppositories, foil-wrapped, with inserter. *Federal law prohibits dispensing VAGISEC PLUS suppositories without prescription. More detailed professional information available on request.*

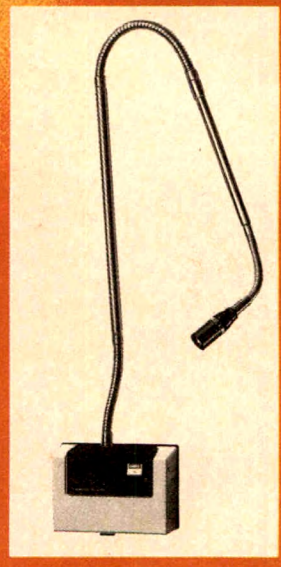
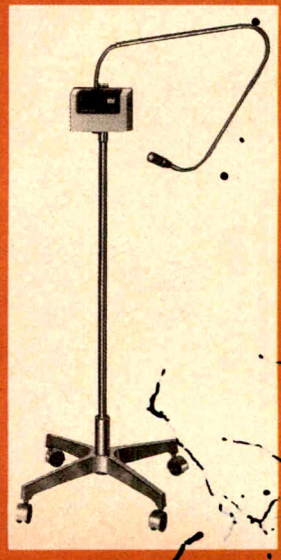
Welch Allyn introduces a light source... second only to the sun.

The NEW Halogen Exam Lite™



Welch Allyn's new Halogen Exam Lite brings Halogen illumination out into the open for the first time.



It's perfect for offices and exam areas where accurate illumination is needed.

A general purpose illuminator that offers economy, efficiency, convenience, versatility, and all the benefits of Halogen lighting.

- ☐ HALOGEN ILLUMINATION—An intense Halogen lamp for brilliant light. 3,100°K, 3,500 ft. candles (37,500 lumens per sq. meter) at a distance of 4 in. (10 cm.), life 50 plus hours
- ☐ FIBER OPTICS—Obedient, yet flexible fiber optics yield even and cool illumination at the distal end. 48 in. (122 cm.)
- ☐ LITE BOX—A cool and quiet lite box, no fan or noise, designed to complement any decor (UL and CSA approved)
- ☐ LENS SYSTEM—A small easy-to-use lens focussing system for adjusting and concentrating the light spot
- ☐ SHEATH—A disposable, clean sheath that prevents contamination
- ☐ MODES OF USE—Mount on wall, exam table, desk or use as a portable unit mounted on a mobile stand
- ☐ EFFICIENT—Economically efficient; draws only 30 watts of power while providing the finest diagnostic lighting available

Contact your Welch Allyn dealer for a demonstration today!

A low level
of estrogen with
a high level of
patient acceptance

"In deciding which combination drug to initially prescribe it is best to utilize the combination pill with the lowest effective dose and an acceptable level of side effects."

Mishell, D.: Current Status of Oral Contraceptive Steroids, Clin. Obstet. Gynecol. *19*:743-764 (December) 1976.

Choose an oral contraceptive - she'll stay with.

- Proven effectiveness with excellent cycle control
- Low dropout rate due to breakthrough bleeding and spotting (based on 2,256 patients)*

Months of use	1	2	3	6	9	12
Discontinuation (cumulative) per 100 woman-years of use	0.7	1.1	2.0	3.0	3.5	4.2

*Data on file, G. D. Searle & Co.

- Minor side effects uncommon
- Low incidence of cramping, nausea, weight gain, breast tenderness, and irritability
- Simplified schedule with calendarized Compack®
- Excellent record of continuation

Please see the next page for a brief summary of prescribing information.

Demulen®

(ethynodiol diacetate 1 mg., ethinyl estradiol 50 mcg.)

...She'll stay with it.

Serious as well as minor side effects have been reported with the use of oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptoms of serious disease or conditions and discontinue oral contraceptive therapy when appropriate. The physician should be fully familiar with the complete prescribing information for this product.

SEARLE

Indication and usage—For prevention of pregnancy. Pregnancy rate using products with ≥35 mcg. ethinyl estradiol or ≥50 mcg. mestranol is <1/100 woman-years. With ≤35 mcg. ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. Dose-related Thromboembolic Risk—One study showed positive association between OC estrogen dose and thromboembolic risk. Thus, it is prudent and in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing the least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new OC users on ≤50 mcg. estrogen.

Contraindications—Thrombophlebitis, thromboembolic disorders, cerebral vascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal vaginal bleeding; markedly impaired liver function; past or present, benign or malignant liver tumors.

Warnings

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke.

OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. Thromboembolic disorders and other vascular problems—Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased relative risk for fatal venous thromboembolism, 2 British and 3 U.S. studies increased relative risk for nonfatal venous thromboembolism. Two U.S. studies showed increased relative risk for stroke, not shown in prior British studies. It was estimated OC users were 2–11 times more likely than nonusers to manifest these diseases without evident cause. In a British study of idiopathic deep vein thrombosis and pulmonary embolism, projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. In a British mortality study, overall excess mortality from pulmonary embolism or stroke was 1.3–3.4 deaths/year/100,000 users and increased with age. Cerebrovascular Disorders—In a U.S. study of stroke with and without predisposing causes, risk of hemorrhagic stroke was estimated as 2 times greater and thrombotic stroke 4.0–9.5 times greater in users. Mortality trends in 21 countries indicate that, since OC introduction, changes in mortality from nonrheumatic cardiovascular disease were associated with changes in the prevalence of OC use. The Royal College of GPs reported on its prospective study comparing users and nonusers: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." They reported more superficial and deep vein thrombosis in users. A 1977 analysis showed a 5-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age, smoking and duration of use. In 1976 a British Family Planning Association study found a highly significant association between OC use and stroke though total numbers were small; the increased risk for venous thrombosis and pulmonary embolism was about 4-fold and statistically highly significant. Circulatory disease mortality was significantly greater in users. Myocardial Infarction—An increased risk of MI associated with OC use was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the MI risk, regardless of OC use. OCs were considered an additional risk factor. The excess rate of fatal MI in Britain was about 3.5/year/100,000 users aged 30–39 and 20 for ages 40–44. (These are based on British vital statistics with acute MI death rates 2–3 times less than the U.S. Similar estimates for U.S. are 25.7 for users aged 30–39 with predispositions vs. 1.5 without; for ages 40–44, 86.2 vs. 5.1.) Excess hospitalization rate for nonfatal MI in Britain was about 3.5/year/100,000 users aged 30–39 and 47 for ages 40–44. Smoking is a major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk of fatal MI as nonsmoking users, but a 10–12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30–39		Aged 40–44	
	Users	Nonusers	Users	Nonusers
All smokers	10.2	2.6	62.0	15.9
≥15 cigarettes daily	13.0	5.1	78.7	31.3
<15 cigarettes daily	4.7	0.9	28.6	5.7
Nonsmokers	1.8	1.2	10.7	7.4
Smokers and nonsmokers	5.4	1.9	32.8	11.7

Risk of Dose—Reports of thromboembolism after use of OCs with ≥50 mcg. estrogen received by drug safety committees in Britain, Sweden and Denmark were compared with the distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of thromboembolism, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg. estrogen were associated with higher thromboembolism risk than those with 50–80 mcg. The authors suggested that estrogen quantity may not be the sole factor. Any influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing the same estrogen dose nor between ethinyl estradiol and mestranol. Studies on thromboembolic risk with progestogen-only OCs have not been done. Cases have been reported for these OCs and they are not presumed free of excess risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of thromboembolism was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg. and those with ≥100 mcg. estrogen. For all cases combined, larger doses were associated with only slightly higher relative risk; for idiopathic cases relative risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was no increased risk for cases with predispositions. Thromboembolic risk in users and nonusers increases with age. OCs have been considered an independent risk factor. Excess Mortality from Circulatory Diseases—A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers according to age, smoking habits and duration of use. Excess mortality was 20/100,000 users (5 for ages 15–34, 33 for ages 35–44, 140 for ages 45–49), the risk being concentrated in older women, long-term users, and smokers. Interrelationships of age, smoking and duration of use could not be examined, nor could effects of continuous vs. intermittent use. Though circulatory mortality was increased 10-fold in users of >5 years, all deaths were in women over age 34. Until more under-35 users of 5+ continuous years are available, size of relative risk for this age group cannot be given. Risk of circulatory disease may have persisted after discontinuance of OCs. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (e.g., thromboembolism for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers as a class, light smokers about half. Mortality associated with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with the condom or diaphragm backed up by early legal abortion. Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high, B—high, C—moderate, D—low. Age:	<30	30–39	≥40
Heavy smokers (≥15/day)	C	B	A
Light smokers (<15/day)	D	C	B
Nonsmokers, no predispositions	D	C,D	C
Nonsmokers, with predispositions	C	C,B	B,A

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary artery disease, myocardial infarction, retinal thrombosis, mesenteric thrombosis). Should any of these occur or be suspected, discontinue OCs immediately. A 4–7-fold increased risk of postsurgery thromboembolism was reported in users; if feasible discontinue OCs at least 4 weeks before elective surgery or during prolonged immobilization and do not resume until at least 4 weeks postsurgery. Thromboembolic risk may be increased for users with blood types A, B or AB. 2. Ocular lesions—Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. 3. Carcinoma—Long-term estrogen in certain animals increases carcinomas such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is no evidence that estrogens increase risk of human endometrial carcinoma. In several case-controlled studies increased relative risk (3.1–13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in 8 U.S. areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions (e.g., irregular bleeding before OCs, polycystic ovaries) occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometrial cancer with combination or progestogen-only OCs, though individual cases have been reported. Studies show no increased breast cancer with OCs or estrogens. However, greater risk was noted in OC users with benign breast disease or long-term (2–4 years) use. Risk of breast cancer with menopausal estrogens rose and further increased with duration of follow-up. Decreased benign breast tumors in OC users is well known. Some studies suggested increased risk of cervical dysplasia, erosion and carcinoma in long-term users; cause and effect is not established. Cervical microglandular hyperplasia has been reported. In summary, there is no confirmed evidence from human studies of increased cancer risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nonfunctional causes and take appropriate diagnostic measures to rule out malignancy. Carefully monitor users with a strong family history of breast cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasia. 4. Hepatic adenomas, hepatomas, hamartomas, regenerating nodules, focal nodular hyperplasia, hemangiomas, hepatocellular carcinoma, etc. have been associated with OCs. In 1 study OC formulations with high "hormonal potency" were associated with higher risk. Though benign these hepatic lesions may rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Consider such lesions in users with abdominal pain, tenderness, mass or shock. About 25% present with abdominal masses; up to half with acute hemoperitoneum. Routine radiologic and lab studies may not be helpful; liver scans may show a focal defect. Hepatic arteriography or CAT may be useful in diagnosis. Hepatocellular carcinoma was noted in a few users. OCs are contraindicated in case of past or present, benign or malignant liver tumors. 5. Use in or immediately preceding pregnancy, birth defects, malignancy in offspring—Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. From 30–90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. Males so exposed may develop urogenital defects. Other estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, e.g., multiple anomalies described by VACTERL for vertebral, anal, cardiac, tracheoesophageal, renal and limb defects. There appears preferential expression by males. There was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal pregnancy tests or treatment for threatened abortion). Some exposures were very short, being only a few days. Cardiovascular defects in children exposed to female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8 for those unexposed (P<.05). Female sex hormones were used for threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming pregnant soon post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon after stopping OCs. Safety of OCs in pregnancy has not been demonstrated. Rule out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods are missed rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. If pregnancy is confirmed, apprise patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregnancy tests. 6. Gallbladder disease risk, surgically confirmed, appeared after 2 years' use and doubled after 4–5 years in 1 study; it appeared in 6–12 months' use in another. 7. Carbohydrate & lipid metabolism—Decreased glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglycerides and total phospholipids may increase. 8. Elevated blood pressure (BP) occurs in some users in a few months, and degree may relate to progestogen dose. Hypertension prevalence in users is no higher than in nonusers in the first year, but increases with longer exposure; in the 5th year it is 2½–3 times the first year. Age is strongly correlated with hypertension in users. Those with history of elevated BP (hypertension), pre-existing renal disease, history of toxemia or elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during menstrual cycles may be more likely to develop elevated BP on OCs and thus should be monitored closely. Even though elevated BP may be in the "normal" range, do not ignore clinical implications. Follow closely, particularly those with other risk factors for cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. 9. Headache—Onset or exacerbation of migraine or development of headache of a new pattern that is recurrent, persistent or severe requires stopping OCs and evaluating cause. 10. Bleeding irregularities—Breakthrough bleeding (BTB), spotting and amenorrhea are frequent reasons for discontinuing. In BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to a higher estrogen OC only when necessary as this may increase thromboembolic risk. Those with a history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patients with postpill amenorrhea when galactorrhea was present. 11. Ectopics—In failures with combination OCs, the ratio of ectopic to intrauterine pregnancies is no higher than in nonusers. There may be an increased risk of ectopics after discontinuing. 12. Breast feeding—OCs may decrease quantity and quality of milk. A small fraction of OC steroids appears in milk. Effects if any on the child are unknown. If feasible defer OCs until after weaning. 13. Infertility may occur in women discontinuing OCs, which appears independent of duration of use. While impairment diminishes with time, there is still an appreciable difference in nulliparous but not parous women after 30 months; difference is negligible after 42 months.

Precautions—Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen and pelvis, with BP, pap and lab tests. Pre-existing uterine leiomyomata may enlarge. Mental depression may occur; with positive history, observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma, or cardiac, hepatic or renal dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observe carefully and discontinue if jaundice occurs. Steroids may be poorly metabolized in liver dysfunction and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblastic anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T_4); decreased T_3 uptake, unaltered free T_4; decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceride, phospholipid; reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged OC use on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response is not established. OCs may mask onset of climacteric. Information for patients—see patient labeling. Drug interactions—OC effectiveness may be decreased and more BTB occur with rifampicin, isoniazid, ampicillin, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of drugs such as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensives, vitamins, hypoglycemics.

Adverse Reactions—Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis and thrombosis; pulmonary embolism; myocardial infarction and coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding; congenital abnormalities. There is evidence of association between the following conditions and OCs, though confirmatory studies have not been done: mesenteric thrombosis; Budd-Chiari syndrome, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following have been reported with OCs and are believed drug related: nausea, vomiting, gastrointestinal symptoms, breakthrough bleeding, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargement, secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. The following have been reported and association has not been confirmed or refuted: premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, itching, vaginitis, porphyria, impaired renal function, anemia, pancreatitis, hepatitis, colitis, gingivitis, lupus erythematosus, rheumatoid arthritis, pituitary tumors (e.g., adenoma) with amenorrhea and/or galactorrhea after use, endometrial, cervical and breast carcinoma.

Acute overdosage—Serious ill effects have not been reported after large acute doses of OCs in young children, but nausea and withdrawal bleeding might occur.

Important note—Full prescribing information should be consulted prior to use and is available on request.

Demulen® Each white tablet contains ethynodiol diacetate 1 mg. and ethinyl estradiol 50 mcg. Each pink tablet in Demulen-28® is a placebo containing no active ingredients.

"Nonspecific" vaginitis is often masked
"Nonspecific" vaginitis
...Often masked by previsit and routine douches, candidiasis and trichomoniasis.[1]
...Often chronic—in a recent clinical study of 5,000 consecutive cases of chronic vaginitis, the chief cause was undiagnosed H. vaginalis vaginitis, followed by candidiasis and trichomoniasis.[1]
1. Fleury, F.J.: Obstet. Gynecol. News 12:1,25, Aug. 15, 1977.
2. Gardner, H.L., and Kaufman, R.H.: Benign Diseases of the Vulva and Vagina, St. Louis, The C.V. Mosby Company, 1969, p. 191.

When you unmask "nonspecific" vaginitis you may find H. vaginalis

Sultrin
TRADEMARK

Triple Sulfa Cream/Vaginal Tablets

effective against H.vaginalis— the cause of over 90% of "nonspecific" vaginitis[2]

Effective
Based on a review by the National Academy of Sciences/National Research Council, SULTRIN was rated as "effective" against *H. vaginalis.*

Prompt symptomatic relief
Patients can experience relief of embarrassing itching and malodorous discharge. Within the same time, most patients can also achieve marked clinical improvement.

Versatile adjunct in other vaginitides
SULTRIN is also effective in treating H.V. vaginitis concomitant with trichomoniasis and candidiasis.

Convenient choice of dosage forms
SULTRIN comes as a soothing, nonstaining and esthetically pleasing cream or convenient vaginal tablets.

Composition: SULTRIN Cream contains sulfathiazole 3.42%, sulfacetamide 2.86%, sulfabenzamide 3.7%, and urea 0.64%. Each SULTRIN Tablet contains sulfathiazole 172.5 mg, sulfacetamide 143.75 mg, and sulfabenzamide 184.0 mg.

Indications: SULTRIN Cream and Tablets are indicated for treatment of *Haemophilus vaginalis* vaginitis. They may also be used as a deodorant for saprophytic infection following radiation therapy.

Contraindications: Sulfonamide sensitivity and kidney disease.

Dosage: SULTRIN Cream: One applicatorful intravaginally twice daily for 4 to 6 days. The dosage may then be reduced one-half to one-quarter.
SULTRIN Tablets: One tablet intravaginally before retiring and again in the morning for ten days. This course may be repeated if necessary.

Supplied: SULTRIN Cream is available in 2.75 oz. (78 g) tubes with the ORTHO* Measured-Dose Applicator.
SULTRIN Tablets are available in packages of 20 foil-wrapped tablets with vaginal applicator.

OBSTETRICIANS.

Because of our hospital expansion program, Aramco needs obstetricians to provide medical care for our overseas community. You should be American Board certified or Board eligible.

Work in our JCAH hospital.

Our hospital, currently expanding to 370 beds, is located in Dhahran, Saudi Arabia, and is one of the few outside the U.S. accredited by the JCAH. You'll find it equipped with the latest medical reference library, equipment and special care units, including surgical and medical ICU, coronary care, labor and delivery and burn treatment units.

Who is Aramco?

We are the world's largest oil-producing company, working to develop the energy resources of Saudi Arabia.

Why work for Aramco?

Besides the challenge and career opportunities of your job, working for Aramco overseas offers several excellent advantages. You'll receive a good salary and savings plan, plus a generous tax-protected expatriate premium.

And you can travel the world if you wish, because on the average of every 12½ months, you receive 40 fully paid vacation days, as well as round-trip vacation travel fare to the U.S. Add to this an average of 12 paid holidays each year.

In addition, Aramco offers a generous retirement plan, excellent recreational facilities and free medical care for you and your family while in Saudi Arabia.

Call us toll free.

If you would like to know more about what we can offer you, call Velma Guy toll free at 1-800-231-7577, ext. 4155 or collect at 0-713-651-4155.

If you prefer, send your curriculum vitae in confidence to Aramco Services Company, Dept. AJOG0500-79A, 1100 Milam Building, Houston, Texas 77002. No obligation, of course.

ARAMCO
SERVICES COMPANY

AMI owns and manages community hospitals throughout California. Our professional relations staff can provide you with information pertaining to your area of interest. Please send your curriculum vitae in strictest confidence, or contact:

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.95 each, postpaid (3 for $14., 6 for $24.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

An effective nonhormonal contraceptive answers these concerns:

"I'm worried about taking the pill."

"I can't use an IUD."

CP24,273

"The diaphragm is just too much trouble."

If she finds her contraceptive difficult—or feels it might be dangerous—she may not use it. That's probably why an increasing number of physicians are recommending ENCARE. So simple, it actually encourages the regular use necessary for effectiveness. And ENCARE is free from systemic side effects.

A new level of convenience

ENCARE is smooth and small for quick, easy insertion without applicators or devices. Each ENCARE insert is individually packaged for discreet portability. Spermicidal protection occurs ten minutes after insertion and lasts for one hour. Because ENCARE may be inserted in advance, it need not be interruptive.

A high level of effectiveness

ENCARE contains a premeasured dose of the potent spermicide nonoxynol 9 to immobilize sperm on contact. Introduced into the vagina as a solid insert, ENCARE gently effervesces in situ, dispersing a spermicidal foam across the cervical os. This provides highly reliable spermicidal protection against pregnancy, when properly used. However, no contraceptive method provides an absolute guarantee against becoming pregnant.

For all her fertile years

Since ENCARE contains no hormones, it does not disrupt body chemistry. That's why it is a rational alternative when contraceptive choice is influenced by health, age or maturity of patient. For patients in whom pregnancy is contraindicated or poses a special risk, the contraceptive program should be individualized by the physician.

As ENCARE effervesces there may be some sensation of warmth; however, this should not be a cause for concern. Burning and/or irritation of the vagina or penis has been reported in a limited number of users of vaginal contraceptives, containing nonoxynol 9, including ENCARE. If this occurs, product use should be discontinued.

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

> *"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."*

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

By Lois DeBakey, Ph.D. In collaboration with: Paul F. Cranefield, M.D., Ph.D.; Ayodhya P. Gupta, M.D.; Franz J. Ingelfinger, M.D.; Robert J. Levine, M.D.; Robert H. Moser, M.D.; J. Roger Porter, Ph.D.; and F. Peter Woodford, Ph.D. August, 1976. 128 pages, 6″ × 9″. Price, $12.50.

Information for authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

All articles published in this JOURNAL must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority.

Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article. They should include name of author(s), article title, name of periodical, volume, page, and year. Name of periodical should conform to that shown in latest *List of Journals Indexed in Index Medicus*. For reference style see current issue of JOURNAL. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2*, Current Investigation and Clinical Opinion, limited to *6*, and Current Developments, for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. **Do not send original art work, x-ray films, or ECG tracings.** Glossy print photographs are preferred, for good black and white contrast is essential.

Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the JOURNAL but may be submitted for paid advertisements, if desired.

Letters to the Editors. A brief Letter to the Editors commenting upon some article which has appeared in the JOURNAL will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

Nature provided
estradiol then...
Estrace provides
it now

Estradiol...the only estrogen necessary in estrogen replacement therapy

ESTRACE®
(ESTRADIOL)

1-mg. and 2-mg. scored tablets

Estradiol, the active estrogen at the cellular level

Estradiol is the primary estrogen of the human ovary—estrone and estriol are considered its oxygenated metabolites[1]—and the major estrogen secreted during the reproductive life of the woman.[2]

Estradiol, not estrone, is the logical estrogen to replace

At menopause the normal cyclical production of estradiol declines, resulting for many women in the unpleasant symptoms of estrogen deficiency—hot flushes and atrophic vaginitis being the most common. ESTRACE provides the estradiol the ovary produced in the premenopausal years.

ESTRACE...the orally effective estradiol

Estradiol was long thought desirable in oral estrogen replacement therapy, but administration was not practical owing to erratic absorption. With the technique of micronization, dependable oral absorption has been demonstrated.[3,4]

ESTRACE is rapidly absorbed, active at the cellular level, and follows the normal metabolic pathways in its utilization by the body. ESTRACE provides objective[4] and clinical evidence[3] of ready availability and biologic activity because estradiol can be assayed in plasma.

Easy to titrate to lowest effective dosage

ESTRACE is easy to titrate up or down as necessary for the individual patient to arrive at the lowest effective dose as soon as possible. Available in 1-mg. and 2-mg. *scored* tablets, ESTRACE is usually effective in a single dose of 2 mg. per day, administered on a cyclic basis.

Mead Johnson
PHARMACEUTICAL DIVISION

ESTRACE® (ESTRADIOL)

Estradiol...the only estrogen necessary in estrogen replacement therapy

1-mg. and 2-mg. scored tablets

Warning

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods.[1-3] This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.[4] The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment[1] and on estrogen dose.[3] In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration;[3] it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY. The use of female sex hormones, both estrogens and progestagens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare.[5,6] This risk has been estimated as not greater than 4 per 1000 exposures.[7] Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis,[8-12] epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects.[13-16] One case control study[16] estimated a 4.7-fold increased risk of limb reduction defects in infants exposed *in utero* to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestagens are effective for these uses. If Estrace® is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation.

Clinical Pharmacology— 17β-Estradiol is the most potent physiologic estrogen and, in fact, is the major estrogenic hormone secreted by the human. Estradiol in Estrace® has been micronized and demonstrated to be rapidly and effectively absorbed from the gastrointestinal tract.[17]

Indications: Estrace® is indicated in the treatment of: 1. Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.) 2. Atrophic vaginitis. 3. Kraurosis vulvae. 4. Female hypogonadism. 5. Female castration. 6. Primary ovarian failure. ESTRACE® HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Contraindications: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients with progressing inoperable or radiation resistant disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (See Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

Warnings: There is now evidence that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.) At the present time there is no evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. However, women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms should be administered an estrogen with caution and a careful breast examination should be performed. A recent study has reported a 2 to 3-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens.[18] An increased risk of post-surgery thromboembolic complications has been reported in users of oral contraceptives.[19,20] If feasible, estrogen should be discontinued at least 4 weeks before, and not resumed until at least 4 weeks after, surgery of the type associated with an increased risk of thromboembolism. Estrogens should not be used in persons with thromboembolic disorders and they should not be used (except in treatment of malignancy) in persons with a history of such disorders in association with estrogen use or in patients with cerebral vascular or coronary artery disease. Benign hepatic adenoma should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepato-cellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives.[21] The relationship of this malignancy to these drugs is not known at this time. There is now evidence that elevated blood pressure occurs with use of estrogens in the menopause[22] and blood pressure should be monitored with estrogen use, especially if high doses are used. Diabetic patients taking estrogens should be carefully observed for decrease in glucose tolerance. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

Precautions: A complete pretreatment and periodic physical examination should be given to estrogen users with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. Conditions which might be influenced by fluid retention such as epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Patients with a history of depression should be carefully observed. Preexisting uterine fibromyomata may increase in size while using estrogen. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be administered with caution in patients with impaired liver function. Estrogens should be used with caution in patients with metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency. Estrogens should be used judiciously in young patients in whom bone growth is not complete. The following endocrine and liver function tests may be affected with larger doses of estrogen: a. Increased sulfobromophthalein retention; b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability; c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radicimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered; d. Impaired glucose tolerance; e. Decreased pregnanediol excretion; f. Reduced response to metyrapone test; g. Reduced serum folate concentration; h. Increased serum triglyceride and phospholipid concentration. As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

Adverse Reactions: The following additional adverse reactions have been reported with estrogenic therapy, including oral contraceptives: Breakthrough bleeding, spotting, change in menstrual flow; Dysmenorrhea; Premenstrual-like syndrome; Amenorrhea during and after treatment; Increase in size of uterine fibromyomata; Vaginal candidiasis; Change in cervical eversion and in degree of cervical secretion; Cystitis-like syndrome; Tenderness, enlargement, secretion of the breasts; Nausea, vomiting; Abdominal cramps, bloating; Cholestatic jaundice; Chloasma or melasma which may persist when drug is discontinued; Erythema multiforme; Erythema nodosum; Hemorrhagic eruption; Loss of scalp hair; Hirsutism; Steepening of corneal curvature; Intolerance to contact lenses; Headache, migraine, dizziness; Mental depression; Chorea; Increase or decrease in weight; Reduced carbohydrate tolerance; Aggravation of porphyria; Edema; Changes in libido.

Overdosage: Serious ill effects have not been reported following the ingestion of large doses of estrogen-containing oral contraceptives by young children. Overdosage of estrogen may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration: 1. *Given cyclically for short term use only:* For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause. The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (e.g., 3 weeks on and 1 week off). Attempts to discontinue or taper medication should be made at 3 to 6 month intervals. The usual initial dosage range is 1 or 2 mg. daily of micronized estradiol adjusted as necessary to control presenting symptoms. The minimal effective dose for maintenanace therapy should be determined by titration.

2. *Given cyclically:* Female hypogonadism; female castration; primary ovarian failure. Treatment is usually initiated with a dose of 1 or 2 mg. daily of micronized estradiol, adjusted as necessary to control presenting symptoms; the minimal effective dose for maintenance therapy should be determined by titration.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

DIRECTOR OBSTETRICS AND GYNECOLOGY

Full time, Waterbury Hospital. Yale University Affiliated 500 bed teaching hospital. To direct training of Yale Obs/Gyn residents and medical students. To help ensure high quality of patient care. To coordinate continuing education for physicians in practice. Hospital also has residency programs in Medicine, Surgery, Pediatrics, Radiology, Urology and Orthopedics with relationships with Yale or University of Connecticut. Medical students from Yale, U. Connecticut, Dartmouth, other schools receive training at W.H. Salary competitive, excellent fringe benefits, referral private practice permitted. Yale Clinical Faculty Appointment. Prerequisites: Academically oriented, board certified skilled clinician and teacher with administrative experience and/or ability. Three or more years experience as full time or clinical faculty member of a medical school. Some practice experience desirable. For further details send CV to: Thomas T. Amatruda, Jr., M.D., Clinical Director, Waterbury, CT 06720. W.H. is an equal opportunity employer.

GROUP HEALTH PLAN

Minneapolis/St. Paul Minnesota

A growing, 20 year old prepaid multispecialty group of 100 physicians seeks a board eligible or board certified Obstetrician/Gynecologist to join nine physician department in one of America's leading metropolitan areas. Excellent fringe benefits. Send curriculum vitae to: John W. Harkness, M.D., Group Health Plan, 2500 Como Avenue, St. Paul, Minnesota 55108.

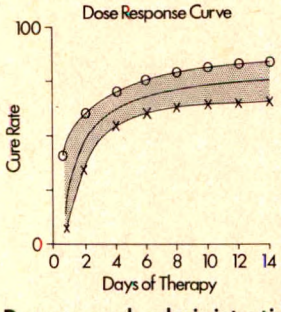
MONISTAT 7 Vaginal Cream
TRADEMARK

(miconazole nitrate 2%)

Description MONISTAT 7 Vaginal Cream (miconazole nitrate 2%) is a water-miscible, white cream containing as the active ingredient, 2% miconazole nitrate, 1-[2, 4-dichloro-β-(2, 4-dichlorobenzyloxy) phenethyl] imidazole nitrate.

Actions MONISTAT 7 Vaginal Cream exhibits fungicidal activity *in vitro* against species of the genus *Candida*. The pharmacologic mode of action is unknown.

Indications MONISTAT 7 Vaginal Cream is indicated for the local treatment of vulvovaginal candidiasis (moniliasis). As MONISTAT 7 Vaginal Cream is effective only for candidal vulvovaginitis, the diagnosis should be confirmed by KOH smears and/or cultures. Other pathogens commonly associated with vulvovaginitis *(Trichomonas* and *Haemophilus vaginalis)* should be ruled out by appropriate laboratory methods. MONISTAT 7 is effective in both pregnant and non-pregnant women, as well as in women taking oral contraceptives. (See **Precautions**.)



Contraindications Patients known to be hypersensitive to this drug.

Precautions General: Discontinue drug if sensitization or irritation is reported during use. Laboratory Tests: If there is a lack of response to MONISTAT 7, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens.

Pregnancy: Since MONISTAT is absorbed in small amounts from the human vagina, it should be used in the first trimester of pregnancy only when the physician considers it essential to the welfare of the patient. Clinical studies, during which MONISTAT was used for 14 days, included 209 pregnant patients. Follow-up reports now available in 117 of these patients reveal no adverse effects or complications attributable to MONISTAT therapy in infants born to these women.

Adverse reactions During clinical studies with MONISTAT for a 14-day regimen, 39 of the 528 patients (7.4%) treated with MONISTAT reported complaints during therapy that were possibly drug-related. Most complaints were reported during the first week of therapy. Vulvovaginal burning, itching or irritation occurred in 6.6%, while other complaints such as vaginal burning, pelvic cramps, hives, skin rash and headache occurred rarely (each less than 0.2% patient incidence). The therapy-related dropout rate was 0.9%.

Clinical Statistical analysis of randomized clinical trials, conducted to determine the shortest effective course of therapy with MONISTAT, demonstrates that a regimen of seven or more days has a cure rate equivalent to the 14-day regimen. The graphic representation of this conclusion plots days of therapy versus cure rates. The solid line represents the mean therapeutic cure rate and the shaded area represents the 95% confidence interval.

Dosage and administration One applicatorful is administered intravaginally once daily at bedtime for seven days. Course of therapy may be repeated after other pathogens have been ruled out by appropriate smears and cultures.

Supplied MONISTAT 7 Vaginal Cream is available in 1.66 oz. (47 g) tubes with ORTHO* Measured-Dose Applicator. MONISTAT Cream (miconazole nitrate 2%) is a development of Ortho Pharmaceutical Corporation and Janssen Pharmaceutica, Belgium.

*Trademark

Why treat vulvovaginal candidiasis for 14 days... when you can do it in 7 nights.

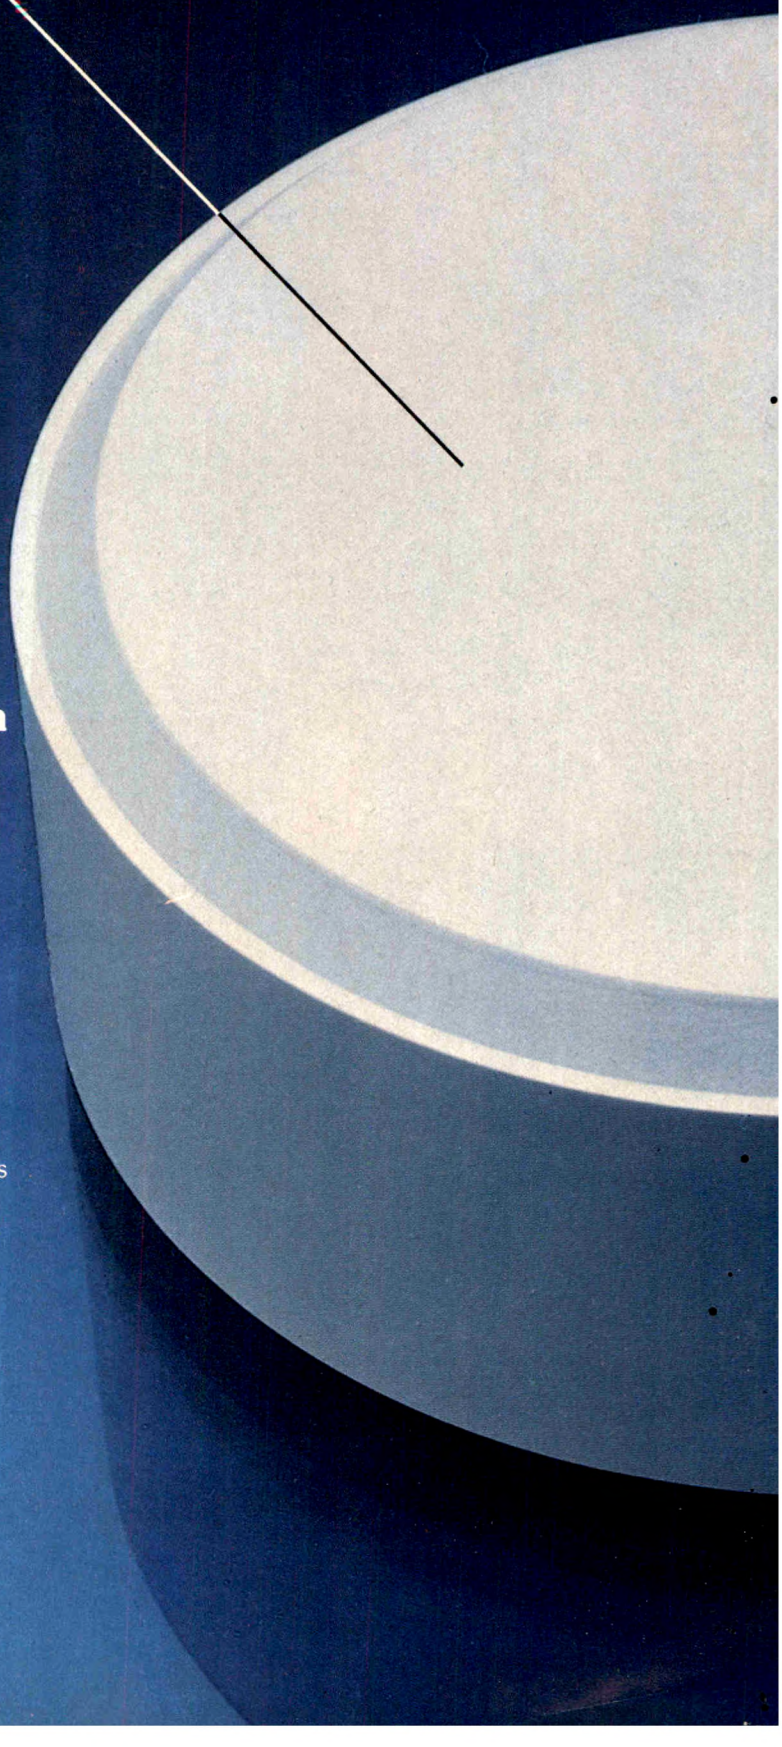
High cure rates in only 7 nights Just one applicatorful of MONISTAT 7 Vaginal Cream, every night, for just 7 nights, produces significantly high cure rates in both pregnant† and non-pregnant patients. Cured patients remained symptom-free with negative cultures throughout the menstrual cycle, i.e., 30 days after completion of therapy.

Greater convenience, better compliance
The short, simple regimen of MONISTAT 7 Vaginal Cream is convenient, easy to comply with, and well-accepted by most women.

Available as a vaginal cream MONISTAT 7 Vaginal Cream rapidly disperses to provide intimate contact with infected tissues. Additionally, a vaginal cream is the most frequently prescribed dosage form.

Monistat 7 TRADEMARK VAGINAL CREAM (MICONAZOLE NITRATE 2%)

high cure rates with only 1 applicatorful (h.s.) for 7 nights



†MONISTAT 7 Vaginal Cream may be used in second and third trimester patients. However, in first trimester patients, it should only be used when the physician considers it essential to the patient's welfare. See Precautions in Prescribing Information.

The progestogen in oral contraceptives
But certainly

Norgestrel, the progestogen that distinguishes Ovral and Lo/Ovral.

Today, many physicians are concerned about choosing a suitable estrogen level for their oral contraceptive patients.

The effects of any combination oral contraceptive, however, are largely the result of the synergistic activity between estrogen and progestogen. So it seems wise to choose the progestogen carefully, too.

Norgestrel, the progestogen in Ovral and Lo/Ovral, has many properties worth examining.

Distinctive because it is non-estrogenic and does not add estrogen. Unlike other progestogens in current use, norgestrel has been shown in biological assays to be free from inherent estrogenicity and does not convert to estrogen *in vivo*. So the delicate estrogen-progestogen balance in Ovral and Lo/Ovral remains undisturbed.

It helps maintain a sound endometrium in combination with ethinyl estradiol. Even at very low doses, norgestrel demonstrates a pronounced ability to help support the integrity of the endometrium—a primary function of progestogen in oral contraceptives.

A highly effective estrogen antagonist. Norgestrel displays marked anti-estrogenic activity at the cervical level. It thickens the cervical mucus during the 3-week cycle of therapy and may therefore act as a secondary contraceptive mechanism.

less talked about than estrogen. important.

Norgestrel and ethinyl estradiol: together they usually mean patient confidence, comfort and compliance. In separate clinical trials, overall effectiveness with Ovral over an 8 year period was 99.3 percent; with Lo/Ovral over a 4 year period, 99.7 percent.[1] Both Ovral and Lo/Ovral also offered excellent cycle control and a minimum of common side effects.* The drop-out rate due to breakthrough bleeding for Ovral was only 0.5 percent; for Lo/Ovral, only 1.4 percent.

50 mcg Ovral® and 30 mcg Lo/Ovral®: distinguished by norgestrel.

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. The physician should remain alert to their earliest manifestations and in the event of serious adverse reactions, should avoid any oral contraceptives. Contraindications, Warnings, Precautions, Adverse Reactions, etc. in the accompanying IN BRIEF should be carefully considered.

1. Based on life table method.

See important information on following page.

Wyeth Laboratories
Philadelphia, Pa. 19101

OVRAL®
Each tablet contains 0.5 mg norgestrel with 0.05 mg ethinyl estradiol.

LO/OVRAL®
Each tablet contains 0.3 mg norgestrel with 0.03 mg ethinyl estradiol.

Copyright© 1979, Wyeth Laboratories Div. of AHPC, N.Y., N.Y. All rights reserved.

IN BRIEF:

Indications and Usage—OVRAL® and LO/OVRAL® are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5).

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gall bladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well-established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use, and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group.

Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g. thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially cigarette smoking.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well-documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract.

Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increase in triglycerides and total phospholipids has been observed in patients on OC's; clinical significance of this finding remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease.

Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination.

2. Under influence of estrogen-progestogen preparations, pre-existing uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when relevant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin.

Carcinogenesis—See Warnings on carcinogenic potential of OC's.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses.

The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

OBSTETRICS

Elevated plasma prolactin concentration in cholestasis of pregnancy

T. RANTA
H.-A. UNNÉRUS
J. ROSSI
M. SEPPÄLÄ
Helsinki, Finland

The plasma concentrations of prolactin and estradiol-17β were measured by specific radioimmunoassays in 150 women with normal pregnancies and 76 women with cholestasis of pregnancy. At 33 to 34 weeks of gestation plasma prolactin concentrations were 187 ± 23 ng/ml (mean ± S.E.M.) for normal pregnancy and 341 ± 38 ng/ml for cholestasis ($p < 0.001$). At 35 to 36 weeks they were 254 ± 24 and 355 ± 26 ng/ml ($p < 0.01$), and at 37 to 38 weeks 175 ± 14 and 365 ± 34 ng/ml ($p < 0.001$), respectively. Higher prolactin levels in the cholestasis group were not related to differences in plasma estradiol-17β concentrations. No correlation was found between plasma prolactin and serum aminotransferase levels, or between prolactin levels and placental weight. The mechanisms by which plasma prolactin levels become elevated in cholestasis of pregnancy remain to be elucidated. (AM. J. OBSTET. GYNECOL. 134:1, 1979.)

PLASMA PROLACTIN levels increase progressively during pregnancy.[1–3] This has been ascribed to stimulation of maternal pituitary galactotrophs by placental estrogens. In early pregnancy the prolactin concentration of amniotic fluid considerably exceeds that of maternal or fetal serum.[4, 5] and it has been suggested that the placenta contributes to this elevation.[6, 7]

Only a few reports describe maternal plasma prolactin levels in pathologic states of pregnancy. Elevated concentrations have been claimed to occur in pregnancies with severe pre-eclamptic toxemia,[8] but this has not been found in all studies.[9]

Cholestasis complicates about 1% of all pregnancies in Finland and Scandinavia, and it is characterized by elevated serum aminotransferase levels, itching, and sometimes jaundice.[10] The placenta shows characteristic features of edema in the chorion villi, but otherwise no characteristic changes have been observed in the fetoplacental unit. Cholestasis is associated with an increased frequency of near-term intrauterine fetal

deaths for so far unknown reasons, and attempts at demonstrating impending intrauterine death by biochemical markers have proved unrewarding.[11] In search of biochemical changes in cholestasis of pregnancy we studied the plasma prolactin levels in this pregnancy complication.

Patients and methods

Plasma samples were collected from 150 women with normal pregnancies between 33 and 38 weeks at the Departments I and II of Obstetrics and Gynecology, University Central Hospital, Helsinki. All women were delivered of healthy infants at term. Specimens from these pregnancies served as controls for normal plasma prolactin and estradiol concentrations in late pregnancy. Cholestasis was diagnosed in 76 women. All had elevated serum aminotransferase levels over 50 U/L.[12] Altogether 181 plasma samples from 33 to 38 weeks of gestation were collected from these pregnancies. Plasma samples were stored at −20° C until assayed.

Plasma prolactin levels were measured by a homologous radioimmunoassay (prolactin standard V.L.S.3, National Institute of Arthritis, Metabolism, and Digestive Diseases, Bethesda, Maryland) as described.[13] All samples were measured in the same assay with a 10% intra-assay coefficient of variation at concentrations between 150 and 250 ng/ml. Reportedly human placental lactogen (hPL) does not cross-react with the prolactin assay we used,[14] and we found a 0.1% cross reaction with purified hPL.

Plasma estradiol levels were measured by radioimmunoassay using 2,4,6,7,-^{3}H-estradiol (NET-317, S.A. 110 Ci/mmol, New England Nuclear, Boston, Massachusetts, and antiserum donated by Dr. B. S. Lindberg, Uppsala, Sweden). The specificity of antiserum has been described.[15, 16] The interassay coefficient of variation of 13 assays was 14% at a final concentration of 25 ng/ml.

Student's t test was used for statistical analysis of differences between normal and cholestasis groups. Correlations between individual prolactin and aminotransferase levels, and between prolactin and placental weight, were studied by Spearman correlation analysis.

Results

In normal pregnancy the mean plasma prolactin levels were from 175 to 254 ng/ml in the third trimester. In cholestatic pregnancy the plasma prolactin concentrations were significantly higher than normal at all stages of gestation. The mean levels were from 341 to 365 ng/ml in the third trimester (Table I).

The concentrations of plasma estradiol were similar in normal and cholestatic pregnancy (Table II). Plasma prolactin concentrations were not correlated with serum aminotransferase levels ($R = -0.023$) or with placental weight ($R = 0.185$).

Comment

Our results show that in cholestasis of pregnancy the plasma prolactin concentrations are significantly higher than in normal pregnancy. This does not seem to be related to circulating plasma estrogen levels or to the severity of maternal disease as based on serum aminotransferase levels. Moreover, no correlation was found between the placental weight and maternal plasma prolactin concentrations.

Elevated prolactin levels in cholestasis may be due to decreased elimination or increased synthesis of prolactin. Decreased metabolism of prolactin has neither been confirmed nor excluded. During gestation prolactin is secreted from fetal and maternal pituitary.[1, 2, 7] We are not able to say whether increased pituitary prolactin secretion is responsible for the difference we observed, but disturbance in the neurotransmitter control of pituitary hormone secretion has been suggested to occur in chronic hepatic failure.[17]

Placental synthesis of prolactin has been proposed,[8] and increased placental production of prolactin must be considered, as one possibility. Human placental lactogen has also been found at elevated concentrations in cholestasis of pregnancy.[11] The 0.1% cross reaction with hPL in the prolactin assay was not responsible for the far higher prolactin level seen in these patients.

Further work is now underway to uncover the mechanisms leading to elevated maternal plasma prolactin concentrations in cholestasis of pregnancy, and to find out whether they bear any relationship to the fetal outcome. However, we have seen no intrauterine fetal deaths since we adopted a practice of inducing labor before the onset of the thirty-ninth pregnancy week.

We are grateful to the National Pituitary Agency, National Institute of Arthritis, Metabolism, and Digestive Diseases, Bethesda, Maryland for supplying us with purified prolactin and the antisera, to Dr. B. S. Lindberg, Uppsala, Sweden, for antiestradiol-17β antiserum, and to Ms. Liisa Airas, Ms. Seija Nikunen, and Ms. Anne Mäkelä for technical assistance.

Screening for alcohol-related problems in an outpatient obstetric-gynecologic clinic

MARCIA RUSSELL, PH.D.
LEWIS BIGLER, M.A.
Buffalo, New York

Three methods of screening for alcohol-related problems were tested in 499 of 565 consecutive patients in an obstetric-gynecologic outpatient clinic. The methods included a 31 item self-administered questionnaire, a six-item physician-administered questionnaire, and a blood alcohol test. Medical records were reviewed for mention of conditions sometimes associated with alcohol use. Sixteen percent of the women were heavy drinkers, and 18% were found on screening to be probable or potential problem drinkers. In women under age 40 years heavy drinking was associated with a higher incidence of physical problems sometimes associated with excessive alcohol use, and significantly lower birth weights were observed in infants born to obstetric patients who were positive on screening for alcohol-related problems. (AM. J. OBSTET. GYNECOL. 134:4, 1979.)

THE PRESENT STUDY is the first phase of a program to explore the feasibility of screening obstetric and gynecologic patients for alcohol- and other drug–related problems. This program was initiated in response to data which indicate that these patients may be at high risk for alcohol-related problems. Studies of alcoholic women reveal an excess of obstetric and gynecologic problems, such as repeated spontaneous abortion,[1] postpartum depression,[2, 3] infertility,[1, 4, 5] and hysterectomy.[5] Both cause and effect have been invoked to account for the association. Alcoholism and heavy drinking are linked to a stressful, precipitating factor more often in female than in male subjects,[1–3] and obstetric-gynecologic problems are among those often cited by women as the cause of their chronic, excessive use of alcohol. At the same time, there is evidence that alcohol is a gonadal toxin,[6] and heavy drinking may contribute to obstetric-gynecologic problems in some women. In addition to the potentially harmful effect of alcohol use on women themselves, it has been recently reported that the excessive use of alcohol during pregnancy is associated with the fetal alcohol syndrome, characterized by retarded intrauterine growth, mental retardation, and a distinctive pattern of congenital anomalies.[7]

These are the factors that motivated the present study in which several methods to screen for alcohol-related problems were tested in an obstetric-gynecologic outpatient clinic. This study addresses some of the following questions: Would obstetric-gynecologic patients cooperate in a study of problems related to their use of alcohol? Would they answer honestly? How sensitive and specific are the screening measures tested? Is there any evidence to support the suggestion that obstetric-gynecologic patients are at high risk for alcohol-related problems? Is the use of alcohol significantly related to health problems of patients and their offspring? Do the test results provide support for the incorporation of screening for alcohol-related problems as part of the routine care of the clinic patients?

Methods

The sample consisted of 565 women seen consecutively during the summer of 1975 in the obstetric-gynecologic outpatient clinic of a general hospital in the inner city of Buffalo. Eighty-eight percent of the sample agreed to participate in the study, for a final sample of 499 women. Reasons for refusals included the following, with about 1% to 2% of the population in each group: minors for whom parental consent was not obtained, mentally retarded individuals, people who were too sick, elderly people who were confused or

suspicious, women who thought their husbands would object, and some who were against surveys in general. In fewer than 1% of the cases was there reason to suspect an alcohol problem was related to refusal to cooperate. Women were mainly lower and lower-middle class; approximately 35% were Caucasian and 65% black; 88 were pregnant, and 411 were gynecologic patients.

The screening methods tested are described below.

A self-administered questionnaire. This was completed in about 10 to 15 minutes while the women waited to see their doctors; it consisted of 31 questions: eight on sociodemographic characteristics, one on smoking, 12 on alcohol use, and 10 on alcohol-related problems. Women were considered positive on screening if they reported heavy alcohol use and/or two or more alcohol-related problems.

Heavy alcohol use. Women were asked how often they drank wine, beer, and liquor, and how often they had five or more drinks, three or four drinks, and one or two drinks of each beverage. These questions on the use of alcohol were used to identify heavy drinkers according to three of the most widely used drinking pattern classification schemes.

THE QUANTITY-FREQUENCY-VARIABILITY INDEX (QFV). Heavy drinking ranges from people who drink three times or more daily regardless of quantity to those who drink two to three times a month but who have five or more drinks more than half the time.[8]

THE ABSOLUTE ALCOHOL INDEX (AA). One or more ounces of absolute alcohol per average day is considered heavy drinking. This corresponds to an average daily intake of two cocktails *or* two glasses of wine *or* two and a half cans of beer or *more*.[9]

THE VOLUME-VARIABILITY INDEX (VV). Heavy drinking is defined as an average daily intake of 1.5 drinks or more and five or more drinks at a time at least once in a while.[8]

Alcohol-related problems. The Self-Administered Alcohol Screening Test of Swenson and Morse[10] was adapted for use in a female population by eliminating questions about behavior that is more typical of male than female alcohol abuse, such as having fist fights after drinking. Also eliminated were questions such as those about attendance at Alcoholics Anonymous meetings which might have intimidated some of the patients and which tend to identify individuals whose problems with alcohol had already been recognized and addressed.

The Cage screening test.[11] This is a series of six alcohol-related questions asked by the physician during his examination: two introductory questions and four test questions on alcohol-related problems. Patients who reported two or more problems were considered positive on screening.

Table I. Heavy drinkers among obstetric and gynecologic clinic patients as measured by three classification systems

Drinking classifications defining heavy drinkers	*Obstetric (N = 88)*	*Gynecologic (N = 411)*	*Total (N = 499)*
QFV	8% (7)	15% (61)	14% (68)
AA (ounces per average day)	6% (5)	11% (46)	10% (51)
VV	6% (5)	12% (50)	11% (55)
QFV or AA or VV	9% (8)	17% (71)	16% (79)
QFV and AA and VV	5% (4)	10% (40)	9% (44)

Blood alcohol test. Blood alcohol concentrations were analyzed only for women who were having blood drawn for other purposes; determinations were made for 12% of the study population (62 of 499). Casual blood alcohol levels over 100 mg/100 ml are considered positive screening results.

Medical record review. Patients' records were reviewed for mention of excess use of alcohol or problems related to alcohol, diseases or mental conditions possibly related to the use of alcohol, and results of laboratory tests associated with excess alcohol use (see Appendices). Mention of alcohol-related problems in the chart was considered to be evidence that clinic personnel were aware of a probable or potential drinking problem.

Summary screening score.* In addition to evaluating patients in terms of their scores on individual screening tests, data from all the available sources, the self-administered screening test, the Cage questions, the blood tests, and the medical record review were pooled for an overall summary screening score. The rationale for summarizing the data in this fashion derives from consideration of the recommendations of the National Council on Alcoholism Criteria Committee for the Diagnosis of Alcoholism.[12] The Committee cites disorders such as liver disease, chronic gastritis, peripheral neuropathy, or anemia in a person who drinks regularly as probably indicative of problem drinking, and it further states that laboratory tests associated with these conditions, such as elevated serum glutamic oxalacetic transaminase levels and abnormal blood tests, may arouse suspicion of an alcohol problem. As well as dis-

*Details on construction of the summary screening score are available from the first author.

cussing physiologic and clinical criteria for the diagnosis of alcoholism (Track 1), the National Council on Alcoholism Criteria Committee has identified behavioral, psychological, and attitudinal criteria (Track 2), such as being criticized by one's spouse, which may indicate problem drinking, and it has recommended that criteria from both tracks be sought in making a diagnosis. The self-administered questionnaire and Cage questions provide data on alcohol-related behavioral criteria, and the medical record and laboratory tests provide data on physiologic and clinical criteria; therefore, these data were combined in final evaluation of the patients. Women who were found to have either physiologic/clinical or psychological/attitudinal factors associated with heavy alcohol use were designated probable problem drinkers on the summary screening score.

Analysis of screening results and consultation notes for women who were diagnosed as problem drinkers by the counselors but who were missed by the screening procedures revealed that most were young women (average age 26 years, ±12 [SD]) who were heavy drinkers (average AA 2.5 ounces ± 1.8 [SD]). They had not yet developed physical problems related to their heavy use of alcohol; they had no work or study ambitions to interfere with their drinking; and they associated with people who were not critical of their drinking patterns. Inasmuch as continued heavy use of alcohol seems likely to lead to problems in the future, patients who consumed more than one ounce of absolute alcohol per average day were designated potential problem drinkers on the summary screening score.

In order to validate the screening tests, every tenth patient was asked to stay for a diagnostic consultation with an experienced alcoholism counselor or consultant. The alcoholism counselors were not always available and in some cases patients could not or would not stay to talk with them; therefore, in the latter phase of the

study every fifth patient was asked to stay for a consultation.

In addition to interviewing randomly selected patients, counselors also saw patients for whom the examining physicians requested a consultation, and attempts were made to follow up patients with positive scores on the screening test. In order to avoid possible bias in the counselors' evaluations, it was also planned to schedule follow-up consultations with subjects who had negative findings on the screening tests who were similar to the screen-positive patients in age, race, marital status, and educational background. Difficulties in locating patients for follow-up interviews, plus the unexpected resignation of the key counselor in the program, reduced the number of follow-up interviews that could be completed. Given this limitation, it was necessary to concentrate on the patients who were positive on screening in order to determine whether they would be considered by alcoholism treatment personnel to have alcohol-related problems serious enough to warrant referral. This decision was motivated by concern for the health of patients who scored positively on screening, as well as by the need to validate the screening instruments.

Table V. Comparison of responses to similar questions on self-administered and physician-administered cage screening tests (N = 310)

Question	*Cage: Physician-administered*		
	Yes	*No*	*Total*
Self-administered:			
Feels/ever felt need to cut down on drinking			
Yes	12	33	45
No	9	256	265
Total	21	289	310
Drinks sometimes/ever drinks in the morning			
Yes	2	7	9
No	2	298	300
Total	4	305	309

Despite this departure from the original study design, the potential for bias is limited by the fact that counselors had a list of symptoms to be checked with each patient which provided a framework for consistency in the consultations. Final diagnoses were based on review of the consultative notes by the authors with-

Table VI. Patient classification according to summary screening score and alcoholism counsellors' diagnostic consultation

Summary screening score	*Diagnostic consultation*			*No diagnostic consultation*	*Total*
	Problem drinkers	*Potential problem drinkers*	*No significant alcohol problems*		
Probable problem drinkers	14	0	2	45	61 (12.2%)
Potential problem drinkers	5	10	2	10	27 (5.4%)
No significant alcohol problems	0	3	32	376	411 (82.4%)
Total	19	13	36	431	499 (100%)

out regard to whether a patient had been selected randomly or on the basis of positive screening results. All in all, diagnostic consultations were obtained in 68 cases. Patients who were found to have significant problems related to their alcohol use were given counseling and referred to appropriate community mental health care programs for additional help as needed.

The records of obstetric patients in the screening program were re-reviewed after screening to determine the outcome of their pregnancies. Delivery and birth records were reviewed for those who were delivered, and information was abstracted on complications associated with labor and on the condition of the baby at birth.

Results

The proportions of obstetric and gynecologic patients identified as heavy drinkers according to the three classification systems, singly and in combination, are compared in Table I. Approximately half as many obstetric patients as gynecologic patients drink heavily, regardless of the index used. Overall estimates of heavy drinking in the clinic population range between 10% and 14%. The failure of any one index to identify all heavy drinkers is indicated by the fact that the proportion of patients identified by any one index (16%) and the proportion defined by all three indices (9%) lie outside the range identified by any of the three indices singly.

In Table II the distribution of the drinking patterns among clinic patients, indirectly adjusted for age, race, and sex,[13] is compared with that observed in the general household population in this region.[14] Approximately three times more abstainers than would be expected are seen among both obstetric and gynecologic patients. However, almost as many heavy drinkers as expected are observed.

The proportions of women with various characteristics sometimes related to excessive alcohol use are presented according to age in Table III. Heavy drinking and alcohol-related problems are most prevalent among women age 30 to 39 years, with lower percentages among women who are younger or older, whereas the occurrence of physical and mental conditions sometimes associated with alcohol use tends to increase with age.

According to the summary screening score, which took into consideration all the data available from the screening program, 18% of the clinic population, 11% of the obstetric patients and 19% of the gynecologic patients were defined as probable or potential problem drinkers. Responses to questions about alcohol-related behavior asked in various parts of the screening program are summarized in Table IV. From 2% to 15% of the clinic population reported problems related to their own drinking; 26% reported that their parents had had drinking problems. Among women who were positive on screening, the percent reporting problems related to their own drinking ranged from 72% who were heavy drinkers to 8% whose relatives or friends had sought help for her drinking. Drinking problems among husbands, sibs, and children were not significantly correlated with positive screening scores in this population. The majority, from 59% to 100%, but not all, of the women who had specific problems related to their drinking also had positive scores on the screening program.

The Cage screening instrument was not administered by the examining physicians for 189 (38%) of the study subjects. In cases where the Cage questions were asked, there was a tendency for patients to deny alcohol-related behavior that they had previously reported on the self-administered questionnaire (see Table V). The converse also occurs; in 11 cases women denied a problem on the self-administered questionnaire and reported it to their physicians.

Of the 36 patients found by the alcoholism counselors to have no significant alcohol problem, 32 were

Table VII. Sensitivity and specificity rates for individual screening tests according to alcoholism counselors' diagnoses and summary screening score

Screening test	Positive on screening test (N = 499) (%)	Counsellors' diagnoses (N = 68)		Summary screening score (N = 499)	
		Sensitivity rate (%)	Specificity rate (%)	Relative* sensitivity rate (%)	Relative* specificity rate (%)
Self-administered screening test (N = 499):					
Two or more alcohol-related problems, plus heavy drinking (QFV or AA or VV)	10	56	97	50	99
Heavy drinking only (QFV and AA and VV—QFV or AA or VV)	9-16	59-84	94	50-65	100-95
Two or more alcohol-related problems only	32	56	97	75	77
Physician-administered "Cage" questions (N = 310) (positive responses to two or more of the four test questions)	3†	23	100	24	99
Blood alcohol concentrations (N = 62)	0	0	100	0	100
Review of medical record (N = 499)	5	13	100	25	85
Summary screening score (N = 499)	18	90	88		

*The summary screening score is treated here as a "truer" rather than a "true" measure of problem drinking; hence the terms relative sensitivity and specificity rates are used.

†Among the 310 patients who received this test 5% responded positively.

also so designated by the screening procedure, for an 88% specificity rate* (see Table VI). Of the 32 women identified as problem or potential problem drinkers by the counselors, only 14 scored as probable problem drinkers on screening, for a relatively low sensitivity rate of 44%. If potential and probable problem drinkers are combined, screening procedures identified 29 of the 32 patients also identified by the alcoholism counselors, for a 90% sensitivity rate.†

The percent sensitivity and specificity of the various components of the screening program as measured by comparison with diagnoses of the alcoholism counsellors and with the summary screening score are summarized in Table VII.

The high sensitivity rates indicate that most of the women who scored positively on the various screening tests were considered by the alcoholism counsellors to have significant alcohol-related problems. Positive scores on individual tests also tended to agree well with positive summary screening scores. However, the sensitivity rates of the individual and combined screening methods vary widely, from 0 in the case of blood alcohol concentrations, none of which were elevated, to 90% for the summary screening score. The physician-administered Cage questions and the medical record reviews identified 23% and 13%, respectively, of the probable and potential problem drinkers. Obviously, the summary screening score is not independent of the component parts of the screening program; however, the "relative" sensitivity and specificity rates provide an estimate of the usefulness of the component parts of the screening program in the total clinic population (see Table VII). Heavy drinking comes closest to identifying the same population as that selected by the summary screening score, combining as it does a fairly high relative sensitivity rate, 65%, with a high specificity rate, 95%.

The heavy use of alcohol is positively associated with several physical complaints commonly reported by the obstetric-gynecologic clinic patients, particularly among those under the age of 40: gastrointestinal pain ($P = 0.003$) and obesity ($P = 0.075$) (see Table VIII). There is a significant excess of heavy drinkers among women with one or more of the diseases or conditions sometimes associated with problem drinking ($P = 0.02$).

The etiologic contribution of heavy drinking to ill health cannot be accurately studied in individuals who already have a disease in which the use of alcohol is contraindicated since diagnosis of the disease may have prompted the individual to stop drinking. Thus, one would not expect to find large numbers of drinkers among patients with liver disease or diabetes; however,

*The *specificity* rate indicates the degree to which the screening test correctly identifies people with no significant alcohol-related problems.

†The *sensitivity* rate indicates the degree to which the screening test identifies women who are diagnosed as problem drinkers.

Table VIII. Relationship between drinking patterns and health in obstetric-gynecologic patients under age 40 years

Health conditions	*N*	*Drinking patterns*			*Significance level*
		Abstainers or infrequent drinkers (%)*	*Light or moderate drinkers (%)*	*Heavy drinkers* (%)*

*According to QFV or AA or VV.

drinking is highly significant in those patients who do continue to use alcohol despite medical contraindications.

Pregnancy outcome for the obstetric patients according to the results of screening for alcohol-related problems is summarized in Table IX. Even in this relatively limited study, the difference in average birth weight between offspring of women with and without alcohol-related problems is statistically significant ($P = 0.04$, one-tailed t test) and clinically significant. A multiple regression analysis of the data indicated that maternal age accounted for approximately 1% of the variability in birth weight; the number of cigarettes smoked per day accounted for 1%; and the diagnosis of alcohol-related problems, entered last in the regression, accounted for 6% of the variability. Thus, the difference in birth weight cannot be attributed to maternal age or smoking habits. The occurrence of a stillbirth among the six women with probable or potential alcohol-related problems is consistent with the fetal problems expected in heavy-drinking women.

Comment

The high response rate obtained was very encouraging and indicates that obstetric-gynecologic patients will cooperate in studies of their alcohol use, at least in this setting. The question of "honest" answers is a more difficult one. There is little motivation for women to exaggerate their alcohol intake or to overreport alcohol-related problems; therefore, it is reasonable to suppose that the findings are accurate or are underestimates. While there are undoubtedly clinic patients who minimize their alcohol intake and deny alcohol-related problems, the striking aspect of the present findings is the fact that 18% of the clinic population reported drinking behavior with sufficient honesty to score as probable or potential problem drinkers.

A national survey found an incidence of high-level problem drinking which ranged from a high of 8% in women aged 30 to 39 years to a low of 1% in women over age 60 years.[15] The relationship between problem drinking and age reported in the nation is similar to that observed in the present study. The higher levels seen in the clinic support the suggestion that obstetric-gynecologic clinic patients are at high risk of alcohol-related problems; however, the national survey data are not directly comparable to those of the present study. Based on household interview data, women in the national survey were defined as problem drinkers with a score of seven or more (out of a possible 58) in 11 problem areas ranked according to the number and severity of problems experienced in the three years prior to the interview. No measures of physical or biochemical indicators of heavy alcohol use were available in the national survey. This factor plus the fewer number of problems required for a positive summary screening score in the present study may account in part for the higher levels of probable and potential problem drinkers identified by the screening procedures being tested here. Part of the differences may also be attributable to higher levels of heavy drinking among women in Western New York State compared to the United States as a whole.[14] Finally, individuals in the lower socioeconomic classes tend to report more problems associated with heavy alcohol use than do middle- and upper-class individuals.[16]

In comparing the sensitivity of various tests it was noted that physician-administered tests and review of

Table IX. The relationship of pregnancy outcome to alcohol-related problems as measured by screening in an obstetric-gynecologic outpatient clinic

Group	*Live births*	*Birth weight ±S.D. (grams)*	*Stillbirths*	*Induced abortion*	*Spontaneous abortion*	*Outcome not determined*	*Total*
No significant alcohol-related problems	49	3,166 ± 728	1	11	5	12	78
Probable or potential drinking problems	5	2,563 ± 567	1	1	0	3	10
Total	54	3,109 ± 732	2	12	5	15	88

the medical records identified far fewer probable and potential problem drinkers than did the self-administered questionnaire. This is consistent with previous reports that clients reported larger alcohol intakes in an impersonal, computer-mediated interview than in a person-to-person interview with a physician.[17] It may be that fear of physician censure may prompt women to minimize their alcohol use and related problems and that the self-administered questionnaire seems less threatening, leading to more accurate reporting of alcohol-related behavior. An alternative explanation is that the self-administered questionnaire raised the patients' anxiety levels and motivated denial in response to similar alcohol-related questions asked later by their physicians.

The sensitivity of the Cage screening instrument administered by the physician was also limited by the fact that 38% of the summary sheets were not returned. This may reflect an underlying reluctance on the part of some of the physicians to raise questions regarding alcohol-related problems with their patients on a routine basis. There are undoubtedly valid reasons for this: concern as to the time required, concern that the patient may be offended or less cooperative, and/or failure to remember to ask the question. Such issues may be partly overcome by use of the self-administered questionnaire.

The study findings offer some support for the hypothesis that heavy alcohol use is significantly related to the health of obstetric-gynecologic patients and their offspring, and further exploration of programs to screen routinely for alcohol-related problems in obstetric-gynecologic patients seems warranted. Additional reasons for continuing this research relate to the fact that women with alcohol-related problems tend to be missed by screening programs focused on the work place or on problems that occur outside the home, such as driving while intoxicated. This, plus access to data regarding physical signs and symptoms related to heavy alcohol use, puts the obstetrician-gynecologist in a unique position with respect to the diagnosis of alcohol-related problems in women. Women also tend to be seen in the obstetric-gynecologic setting at a time when they are concerned about their own health or that of their offspring, which may provide the motivation needed to initiate a change in harmful or potentially harmful drinking patterns.

Of particular interest would be trials of these and other screening tests in other regions of the United States and in other obstetric-gynecologic settings, such as private practices. In the longer view, the establishment of routine screening for alcohol-related programs in women must be supported by effective treatment programs. Clearly, there is much need for work in all these areas.

The authors wish to express their gratitude to Dr. Hebe Greizerstein, Research Institute on Alcoholism, for analyses of blood alcohol levels, and to the staff of the Obstetric-Gynecologic Outpatient Clinic at Buffalo General Hospital for their fine cooperation in conducting this study.

Appendix A

The following diseases and conditions are sometimes related to excessive alcohol use:

1. Nausea
2. Gastrointestinal pain—ulcer, dyspepsia, gastritis
3. Tuberculosis
4. Liver disease—hepatomegaly, cirrhosis, hepatitis
5. Anorexia—weight loss
6. Anemia—iron deficiency
7. Dizziness
8. Numbness
9. Fatigue
10. Vocal cord granuloma
11. Obesity
12. Gout
13. Diabetes
14. Hypercholesterolemia
15. Coronary heart disease
16. High blood pressure
17. Repeated infections—colds, urinary tract, vagina
18. Rheumatic heart disease
19. Passing out
20. Neuropathy
21. Seizures
22. Convulsions
23. Difficulty sleeping
24. Trauma—assaults, falls
25. Dupuytrens contracture
26. Hyperflexia—upper extremities
27. Blackouts

*Counted as a major physical condition.

Appendix B

The following abnormal laboratory findings are sometimes associated with excessive alcohol use:

1. Hypoglycemia (serum glucose between 1 and 65 mg/dl)
2. Hyperglycemia (serum glucose over 110 mg/dl and not pregnant)
3. Low chloride (1 to 96 mEq/L)
4. High bicarbonate (30 mEq/L or over)
5. Low potassium (0.1 to 3.6 mEq/L)
6. Elevated serum glutamic oxaloacetic transaminase (34 μM/min. or over)
7. Elevated mean corpuscular volume (95 μ^3 or over)
8. Elevated lactic dehydrogenase (425 μM/min. or over)
9. Elevated alkaline phosphatase (86 μM/min. or over)
10. Elevated bilirubin (1.2 mg/dl or over)
11. Elevated white blood cell count (12×10^3 or over)
12. Low red blood cell count (0.1 to 3.9×10^6)
13. Elevated mean corpuscular hemoglobin (37 $\mu\mu$g or over)

Appendix C

The following mental conditions are sometimes associated with excessive alcohol use (the following conditions only contribute to the summary screening score if the patient reported heavy drinking on the self-administered questionnaire in addition to having mention of the mental condition in her medical record; the two were ascertained separately):

1. Depression
2. Nervousness
3. Anxiety
4. Crying
5. Insecurity
6. Fearfulness
7. Loneliness
8. Suicidal
9. Unable to cope (with family problems)
10. Poor personal hygiene
11. Dull/lack of intelligence
12. Mentally retarded
13. Sociopathic personality
14. Somatization
15. Hears voices
16. Malaise/lethargy/fatigue
17. Under stress
18. Depression/nervousness during pregnancy
19. Poor motivation for self help
20. Immature
21. Withdrawn
22. Neurotic
23. Psychiatric overlap
24. Overly emotional
25. Nervous breakdown
26. Inadequate personality
27. Underlying psychotic illness
28. Psychosis
29. Drug overdose*
30. Drop in libido
31. Dissatisfied life-style
32. Psychiatric disorder
33. Psychiatric illness

The influence of hypophysectomy, adrenalectomy, progesterone, oxytocin, and estradiol on the metabolic fate of ^{3}H-epinephrine in central and peripheral regions during late pregnancy

SIMONE PARVEZ
ABID RAZA-BUKHARI*
GUL ISMAHAN*
Orsay, France

Variations in the metabolic fate of ^{3}H-epinephrine during the last days of pregnancy were determined in seven peripheral organs and three brain regions of the rat. Hormonal treatments were performed during Days 19 to 21 after coitus. Hypophysectomy of the pregnant females on Day 17 after coitus increased the transformation of ^{3}H-metanephrine and ^{3}H-acid metabolites from tracer epinephrine when compared to Day 21 after coitus. Adrenalectomy produced effects similar to those of hypophysectomy as all the peripheral and central regions except the kidney showed an increased rate of ^{3}H-acid metabolite formation but the formation of ^{3}H-metanephrine was increased only in liver, spleen, ovary, uterus, hypophysis, hypothalamus, and brain. Pretreatment with oxytocin decreased the rate of amine metabolism in most of the organs. Progesterone increased the metabolism of tracer epinephrine in the heart, spleen, ovary, hypophysis, and hypothalamus. Estradiol treatment decreased metabolism of ^{3}H-epinephrine to ^{3}H-metanephrine and ^{3}H-acid metabolites in all of the peripheral and central regions with the exception of the hypothalamus. The rate of uptake of ^{3}H-epinephrine was extremely high in hypophysectomized pregnant rats and very low in progesterone-treated females. Results suggest that steroid and peptide hormones play an important role in the control of monoaminergic function during late pregnancy. (AM. J. OBSTET. GYNECOL. 134:13, 1979.)

THE EXACT role of catecholamines in the maintenance and termination of pregnancy has been studied by several authors during the past decade. The consequences of natural variations in epinephrine, norepinephrine, and related metabolites differ from one animal species to another one.[1] More recently the role of endocrine gland secretions in the processes of monoamine synthesis and release and metabolism during the estrus cycle and pregnancy has become a subject of great interest, and it seems certain that the activity of monoaminergic function depends directly on normal neuroendocrine activity.[2, 3] Our recent studies in rats and rabbits during the estrus cycle, pregnancy, and parturition show a direct link between termination of pregnancy and evolution of adrenal and plasma epinephrine and norepinephrine.[3, 4] It was also found that natural variations in transmitter concentrations which occur during pregnancy and parturition result from modifications in steroid hormone concentrations.[4, 5] In a previous study we showed that the uptake and metabolism of exogenously administered ^{3}H-epinephrine is greatly modified during different days of the last trimester of pregnancy in peripheral and central organs.[5] The variations in physiologic accumulation of ^{3}H-epinephrine and its transformation to ^{3}H-metanephrine and ^{3}H-acid metabolites during the last days of pregnancy which we observed on the eighteenth and twenty-first days after coitus and at 0 hour post partum

Table I. The metabolic fate of exogenously administered ^{3}H-epinephrine in the blood, heart, kidney, and brain after different intervals of perfusion of the tracer. Counts per minute per liter or counts per minute per unit weight of the organ show total radioactivity found at each specific interval

Post perfusion time (min.)	*Blood (cpm/L)*	*Heart (cpm/100 mg)*	*Kidney (cpm/100 mg)*	*Brain (cpm/gm)*
2	3,010	14,220	9,000	7,200
20	1,457	9,760	8,600	6,860
120	560	4,896	1,936	6,900

could be correlated with natural modifications of steroid hormonal concentrations.[6]

The present study shows the effects of two days of pretreatment with oxytocin, progesterone, and estradiol upon the metabolic fate of ^{3}H-epinephrine administered on the twenty-first day of pregnancy. The pregnant rats were also hypophysectomized or adrenalectomized on the seventeenth day of pregnancy and the effects of these surgical hormone alterations on metabolism and uptake of ^{3}H-epinephrine were compared with that of nontreated animals.

Material and methods

Albino female rats of Sherman strain were used in all experiments. The weight of the rats ranged from 300 to 350 grams. The animals were housed at a temperature of 21° ± 1° C with exposures to natural light and darkness. The females were impregnated by keeping one male in the cage of seven females from 7 P.M. to 9 A.M. only once. The fertilization was supposed to occur at 2 A.M. This made it possible to estimate the beginning of pregnancy ±7 hours. The females were palpated 14 days later for verification of pregnancy. If they were found to be pregnant, at 2 P.M. they were considered to be 14.5 days pregnant. Under normal conditions parturition took place during 21.5 to 22 days of pregnancy.

Hormone administration, hypophysectomy, and adrenalectomy. The females on Days 19, 20, and 21 after coitus were injected with progesterone retard, Schering, Berlin (6 mg/100 gm subcutaneously) or estradiol retard, Schering, Berlin (0.65 mg/100 gm). Oxytocin (Choay, Paris, France) (1.25 IU/100 gm) was injected only twice on Days 20 and 21 after coitus. The pregnant females on Day 17 after coitus were either hypophysectomized or adrenalectomized under ether anesthesia. The adrenalectomized rats received 0.9% saline for drinking.

^{3}H-epinephrine administration. ^{3}H-DL-epinephrine (specific activity 4 Ci/mM) was obtained from the Centre D'Energie Atomique, Gif Sur Yvette, France, in ampules each containing 1 mCi of ^{3}H-epinephrine as 0.2N acetic acid solution. The contents of each ampule were diluted to 3.33 ml with twice-distilled water at pH 3. On the twenty-first day of gestation the diluted tracer was further mixed with 0.9% saline and perfused intravenously through a saphenous vein. Each rat was perfused with 60 μCi of ^{3}H-epinephrine under light ether anesthesia. The perfusion lasted for one minute. The disappearance of radioactivity in blood, heart, kidney, and brain was determined at various intervals after perfusion to find out the most suitable period with appreciable amount of radioactivity in most of the organs studied (Table I). Twenty minutes was found to be the best time for all comparisons as a significant amount of tracer was present in hypophysis, hypothalamus, and brain at this interval. Previous studies on the metabolic fate of ^{3}H-epinephrine by Axelrod and associates[7] also show a choice of about a similar interval as that used by us. The main aim of the present experiments was to find differences in ^{3}H-epinephrine accumulation and metabolism in pregnant rats subjected to different hormonal treatments. This is why all the comparisons in all the tissues have been made at 20 minutes postperfusion period. Moreover, the rate of disappearance of radioactivity at 2, 20, and 120 minutes after perfusion was the same in the brain and kidney. This was taken as supplementary evidence to limit our study to only one time interval. All of the animals were killed by neck fracture 20 minutes after the perfusion and the tissues were excised immediately, weighed, and transferred to tubes containing 8 ml of ice-cold mixture of 4% trichloroacetic acid plus 1% EDTA. The homogenization was performed in a Sorvall Omni Mixer. The homogenates were centrifuged immediately at 7,000 × g for 10 minutes. The supernate was divided into three portions: 1 ml each for ^{3}H-metanephrine and ^{3}H-acid metabolites and 3 ml for ^{3}H-epinephrine.

Estimation of ^{3}H-epinephrine. ^{3}H-epinephrine in the supernate was assayed by the method of Euler and Lishajko[8] by adsorption on acid-activated aluminium oxide with preference of batch process to columns.[8] The supernate from all organs in a volume of 3 ml was placed in a 5 ml beaker and 0.5 gm of aluminium oxide was added. The extract was placed on a magnetic stirrer, diluted with sodium acetate, 0.2M at pH 8.4, and adjusted to pH 8.4 first with 1N NaOH and finally with 0.01N NaOH. The operation was controlled by a direct-reading pH meter. The suspension was stirred for

three minutes for adsorption of tritiated epinephrine on alumina and centrifuged afterward for three minutes at 5,000 × g. The supernate was discarded and the precipitate was washed with 5 ml of twice-distilled water. After centrifugation for 3 minutes at 5,000 × g, the ^{3}H-epinephrine was eluted with 2 ml of 0.25N acetic acid. The elutes containing ^{3}H-epinephrine were further centrifuged for five minutes at 8,000 × g to spin down the smallest particles of alumina. The aliquot in volume of 0.5 ml was added to a vial containing 10 ml of Bray's phosphor prepared in dioxane. The vials were counted in a liquid scintillation counter for 10 minutes. The extracted counts per minute show direct linearity with the eluted ^{3}H-epinephrine. The recovery was in the range of 75% to 80%. The results have been corrected for this loss.

Determination of ^{3}H-metanephrine. After addition of 0.1 ml of concentrated HCl to 1 ml of supernate of the tissues, the pH of the mixture was adjusted to 10 to 10.5 with 5N NaOH and 1 ml borate buffer at pH 10. Metanephrine was extracted into 3.5 ml of a toluene and isoamyl alcohol (3 : 2) mixture by mechanical shaking for 30 minutes.[7] After centrifugation, a 3 ml aliquot of the extract was transferred to a vial containing 1 ml absolute ethyl alcohol and 10 ml Bray phosphor. The radioactivity was counted for 10 minutes. On these conditions, about 51% metanephrine was extracted into the organic phase. All the values reported are corrected.

Determination of ^{3}H-acid metabolites. One-tenth volume of 1N HCl was added to 1 ml of tissue supernate in a hemolyse tube and extracted with 3.5 ml of isoamyl alcohol.[7] The aqueous phase was removed by aspiration and the extract was washed with 0.5 ml of 0.1N HCl. A 3 ml aliquot of isoamyl alcohol extract was transferred to a vial containing 1 ml of absolute ethanol and 10 ml of Bray phosphor prepared in toluene. The radioactivity was measured in a liquid scintillation counter for 10 minutes. Both 3,methoxy-4-hydroxymandelic acid and 3,4-dihydroxymandelic acid are extracted and measured by this procedure. The recovery was in the range of 60% and the values were corrected for this loss.

Results

Table II shows physiologic accumulation of exogenously administered ^{3}H-epinephrine to pregnant females. Estradiol pretreatment from 19 to 21 days after coitus increased physiologic accumulation of labeled epinephrine in the ovary, uterus, hypothalamus, and liver but the heart, kidney, spleen, adrenals, hypophysis, and the rest of the brain demonstrated a decrease in this accumulation. All the peripheral organs, hypophysis, and the rest of the brain showed decreased rate of ^{3}H-epinephrine accumulation after pretreatment of pregnant females with progesterone. Similar pretreatment of progesterone increased ^{3}H-epinephrine accumulation in the hypothalamus. The preadministration of oxytocin to pregnant females resulted in decreased accumulation of radioactive epinephrine in liver, kidney, adrenals, uterus, hypophysis, hypothalamus, and the rest of brain and decrease in heart, spleen, and ovary. Hypophysectomy of pregnant females at 17 days after coitus produced marked increases in the accumulation of ^{3}H-epinephrine of all the peripheral organs and central regions. The effects of adrenalectomy of pregnant females were different for each organ concerned. After adrenalectomy the heart, liver and hypothalamus showed increase and the kidney, spleen, ovary, hypophysis, and the rest of the brain showed decrease in physiologic accumulation of ^{3}H-epinephrine.

The metabolic transformation of exogenously administered ^{3}H-epinephrine to ^{3}H-metanephrine has been provided in Table III. The effects of hypophysectomy of the pregnant females were more marked than any treatment as all the peripheral and central organs showed an increase in transformation of ^{3}H-epinephrine to ^{3}H-metanephrine. Adrenalectomy also produced effects similar to hypophysectomy as all the organs except the heart and the rest of the brain showed an increase in metabolic transformation of the labeled amine. Estradiol injection from 19 to 21 days after coitus resulted in decreased conversion of ^{3}H-epinephrine to ^{3}H-metanephrine in the heart, liver, kidney, spleen, adrenals, ovary, uterus, hypophysis, and the rest of the brain. Hypothalamus was the only brain region which demonstrated an increase in ^{3}H-metanephrine transformation after estradiol pretreatment of pregnant females. Progesterone treatment to pregnant females resulted in increased formation of ^{3}H-metanephrine in the heart, spleen, ovary, and hypothalamus, but the liver, kidney, adrenals, uterus, hypophysis, and the rest of the brain showed a decreased rate of ^{3}H-metanephrine formation from ^{3}H-epinephrine. Pretreatment of pregnant females with oxytocin produced a decreased rate of this metabolic conversion in all of the organs except the hypophysis and hypothalamus. Table IV provides a comparison between the effects of different hormonal treatments during 17 to 21 days after coitus upon metabolic transformation of exogenously administered ^{3}H-epinephrine to ^{3}H-acid metabolites. Again the effects of each hormonal treatment were well specified in peripheral

the rest of the brain but the hypothalamus showed a decrease in this metabolic transformation. The effects of oxytocin pretreatment were very similar in all the peripheral and central regions as all the tissues showed a decreased rate of ^{3}H-acid metabolite formation from the value of nontreated females. Progesterone administration during 19 to 21 days after coitus increased ^{3}H-acid metabolite formation in the heart, spleen, ovary, hypophysis, and hypothalamus and decreased this formation in the liver, kidney, adrenals, uterus, and the rest of the brain.

Comment

The results of the present investigation show the influence of different hormones and ablation of the hypophyseoadrenocortical system upon processes of monoamine accumulation and metabolic degradation. The effects of progesterone, estradiol, and corticoids upon enzymes of monoamine synthesis and metabolism have been well investigated in normal males and females during the proestrus phase of the estrus cycle.[9, 10] It was found that the effects of these hormones differ to a marked extent according to the physiologic state of the animal.[9, 10] From Tables III and IV it is evident that hypophysectomy and adrenalectomy produce an increased rate of ^{3}H-metanephrine and ^{3}H-acid metabolite formation from ^{3}H-epinephrine. These observations support our previous findings about the role of adrenal glucocorticoids in the maintenance of enzymes monoamine oxidase and catechol-O-methyltransferase. We found that hypophysectomy or adrenalectomy of the adult or fetus results in highly marked and significant increases in the activities of the enzymes monoamine oxidase and catechol-O-methyltransferase in central and peripheral regions.[11] The inhibition of glucocorticoid biosynthesis pharmacologically by pretreatment of metopirone also results in an increased rate of monoamine metabolism.[9]

The administration of estradiol resulted in decreased transformation of ^{3}H-epinephrine to ^{3}H-metanephrine and ^{3}H-acid metabolites in most of the tissues studied. This observation is in agreement with the previous findings about the action of estradiol upon the activity of enzyme monoamine oxidase in cyclic females,[2] as it was found that estradiol inhibits oxidative deamination of monoamines. The pretreatment of progesterone was followed by increases in some tissues and decreases in the other tissues for the process of ^{3}H-acid metabolite and ^{3}H-metanephrine formation. Under normal conditions the administration of progesterone to animals during the estrus cycle results in increased activity of enzyme monoamine oxidase[2] but in a recent study[10] we have shown that this specific action of progesterone to increase the monoamine oxidase activity during the estrus cycle was limited to that specific period only and was dependent upon the ratio of free and bound progesterone. During pregnancy when the natural concentration of progesterone varies to a great extent, the administration of progesterone to pregnant females results in decreased activity of enzyme monoamine oxidase.[10] Oxytocin, which is a neurohypophyseal hormone, acts like estradiol for the metabolism of ^{3}H-epi-

nephrine to ^{3}H-acid metabolites and ^{3}H-metanephrine since the pretreatment of this hormone also resulted in an increased rate of monoamine metabolism. ACTH which is also a neurohypophyseal hormone has an important action on the formation of epinephrine in the adrenal medulla. It was shown that normal function of the adrenal cortex which is maintained by circulating ACTH was essential for the induction of enzyme phenylethanolamine-N-methyltransferase in the adrenal medulla.[12] The lack of ACTH decreases adrenal epinephrine stores and increases related metabolites of monoamines.[12, 9]

The physiologic accumulation of tracer epinephrine varied according to specific treatment and specific tissue. The effects of hypophysectomy were very uniform as all the organs showed decreased accumulation of ^{3}H-epinephrine whereas ocytocine and progesterone pretreatments produced a decreased rate of epinephrine uptake. These differences can be better interpretated if we look into the extensive studies of Iversen.[13] The role of steroid hormones in the processes of catecholamine uptake was also shown recently and it is certain that the rate of amine uptake by a tissue depends upon the intensity of its adrenergic innervation; its histologic status is more valid for the study of uptake kinetics under controlled experimental conditions in vitro.[13] Now it is accepted that the process of uptake$_2$ has a great importance for physiologic accumulation of amines.[13] Uptake of catecholamines by this process is rapidly followed by intracellular catabolism; uptake$_2$ could thus constitute a mechanism for disposing of extracellular catecholamines by an "uptake and followed by metabolism" process, as opposed to classical "uptake and retention" mechanism previously described by Iversen[13] as uptake$_1$. By uptake$_2$ mechanism, the amines are also taken up by a different transport system in various extraneuronal peripheral tissues, such as vascular smooth muscle, cardiac muscle, and certain glandular tissues. In the isolated rat heart, catecholamines are taken up by two uptake processes, distinguishable because of their different kinetic and pharmacologic properties.[13] It seems that the uptake$_2$ process has a lot to do for the regulation of epinephrine metabolism during pregnancy but it still remains a suggestion as in the present study uptake$_1$ and uptake$_2$ were not differentiated. The presence of an extraneuronal uptake mechanism similar to uptake$_2$ process has also been shown in the recent years which can be taken as an important factor for the variations which we observe in different organs to different hormonal pretreatments.

From the present findings it can be assumed that the processes of monoamine accumulation and metabolism can be markedly modified by exogenous administration of different hormones during late pregnancy. Most of the modifications observed follow well-established action of steroid and peptide hormones on the processes of amine uptake and metabolism. These observations provide some biochemical interpretation of the findings of Zuspan and colleagues[14, 15] in human beings about the role of monoaminergic activity in the maintenance of pregnancy.

The authors express their sincere thanks to Dr. Raynaud of the Centre D'Energie Atomique, Service Hospitaliere Frederic Joliot, Orsay, France, for his kind help. The kind and fruitful discussions of Professor M. B. H. Youdim of the Department of Pharmacology, University of Haifa, Israel, are acknowledged with thanks. The generous help and interest of Professor Paul Benoit, Chairman, Department of Physiology, Paris University, is acknowledged with sincere thanks.

Maternal and fetal renin activity and renin and big renin concentrations in second-trimester pregnancy

ROBERT C. FRANKS
ROBERT H. HAYASHI
San Antonio, Texas

Plasma renin activity (PRA) and the concentrations of renin (PRC) and big renin (PBRC) have been determined in maternal and fetal blood, and renin and big renin have been measured in amniotic fluid, at 16 to 20 weeks of gestation. Gradients between peripheral arterial and venous and uterine venous maternal circulation were not apparent for PRA, PRC, or PBRC. PRC and PBRC but not PRA were consistently higher in fetal cord blood than in the maternal compartment. The concentrations of big renin and of renin were tenfold higher in amniotic fluid than in maternal plasma and were significantly correlated in amniotic fluid but not maternal or fetal plasma. (AM. J. OBSTET. GYNECOL. 134:20, 1979.)

IN THE STUDY of maternal-fetal endocrine relationships, hormonal gradients within the maternal circulation and between mother and fetus have established interdependence and independence of the maternal and fetal compartments. Despite studies at various gestational ages of many aspects of endocrine function, data pertaining to maternal and fetal levels of plasma renin activity (PRA) and concentration (PRC) have been limited to term pregnancy,[1-6] and comparable studies from earlier in pregnancy have not been previously reported.

Big renin has been identified in maternal plasma,[7] in amniotic fluid,[7] and in the plasma of normal newborn infants,[8] but possible gradients of plasma big renin concentration (PBRC) within the maternal circulation or between maternal and fetal compartments have not been studied.

In the current study, PRA, PRC, and PBRC have been measured at 16 to 20 weeks from simultaneous samples of the maternal venous and arterial circulation and in paired maternal and fetal blood specimens. In addition, concentrations of renin and big renin have been determined in paired samples of maternal plasma and amniotic fluid.

Material and methods

The protocol for the study was approved by the Institutional Review Board and informed written consent was obtained from all subjects. The 13 subjects were undergoing elective termination of 16 to 20 week pregnancies for psychosocial indications, and the subjects' decisions for termination of pregnancy were made with medical personnel not involved in the study.

Nine subjects underwent abortion-hysterectomy. Antecubital and uterine venous samples were obtained from seven; a radial arterial sample was obtained from one of this group. In one patient, radial arterial and uterine venous samples were obtained, and in one only an antecubital venous sample was obtained. Amniotic fluid was obtained from two subjects. All specimens were obtained immediately prior to removal of the uterus. Fetal blood was obtained in four instances.

Four subjects had therapeutic abortion by intra-amniotic urea-prostaglandin instillation. Samples of antecubital venous blood and of amniotic fluid were obtained immediately prior to the procedure.

Plasma renin activity and the concentrations of renin and big renin (total renin concentration following activation by pH 3.3 and incubation with trypsin, minus the renin concentration) were determined by methods previously described[9] and results expressed as nanograms per milliliter per hour of generated angiotensin I.

Results

Shown in Table I are the results for determinations of PRA, PRC, and PBRC in seven paired samples of peripheral and uterine venous plasma. Mean (±SD)

*Cardiac blood.

values for PRA (7.7 ± 2.9 versus 7.5 ± 1.6) and PRC (17.9 ± 6.3 versus 14.6 ± 6.3) are slightly higher and for PBRC (45.8 ± 31.6 versus 51.6 ± 32.9) are slightly lower in peripheral blood, but the differences are not statistically significant ($p > 0.1$, Student's t test).

In Table II are shown the results of determinations of PRA, PRC, and PBRC in the maternal and fetal circulations. Again, consistent gradients within the maternal circulation are not evident. Although values for PRA are variable, in each instance PRC and PBRC are higher in fetal cord blood than in both arterial and venous maternal plasma. In one fetal subject, cord blood PRC was slightly higher and PBRC twofold higher than in cardiac blood.

Shown in Table III are results for determinations of maternal venous PRC and PBRC and for renin and big renin concentrations in amniotic fluid in six paired specimens. Values for renin concentration in amniotic fluid are fourfold to 24-fold higher (mean, 10.4 not shown) and for big renin, fourfold to 36-fold higher (mean, 10.8, not shown) than in maternal plasma.

The mean (±SD) ratios of big renin:renin (not shown) in maternal plasma (4.7 ± 4.6), cord plasma (3.1 ± 2.1), and amniotic fluid (3.4 ± 1.4) were not significantly different ($p > 0.1$). Determinations of correlation coefficients revealed significant correlation of

the concentrations of big renin and renin in amniotic fluid (r 0.9075; $p < 0.01$) but not in maternal (r 0.1780; $p > 0.1$) or cord blood (r 0.0959; $p > 0.1$).

Comment

In previously reported studies of full-term pregnancies, maternal peripheral arterial[1] and venous[2] PRA have been slightly higher and PRC slightly lower[3] than in uterine blood. As in the current report, where both PRA and PRC were higher in peripheral venous blood, the differences were not satistically significant. The

available data therefore suggest that gradients of PRA and PRC within the maternal circulation do not occur consistently in pregnancy either at 16 to 20 weeks or at term.

Studies of maternal and fetal PRA and PRC at term have yielded variable results.[3] Although higher maternal[4] or fetal[5] PRA has been reported, the method of delivery may partially account for the observed differences.[6] In the current study, fetal PRC (but not PRA) at 16 to 20 weeks gestation was consistently greater than maternal values.

Big renin presumably originates during pregnancy from fetal chorion[3] and has been found in maternal plasma throughout gestation,[7] in amniotic fluid,[7] and in plasma of newborn infants.[8] In the current study the highest concentrations of big renin occurred in amniotic fluid and PBRC was consistently higher in the fetal than in the maternal circulation. Additionally, in one fetal subject, PBRC from cord blood was higher than that from cardiac blood. These observations are compatible with a fetal chorionic source of big renin.

The ratios of big renin to renin in maternal plasma and in amniotic fluid at 16 to 20 weeks in this report are comparable to those previously reported.[7] The positive correlation of big renin and renin concentrations in amniotic fluid at 16 to 20 weeks and at 34 to 37 weeks,[7] but not in maternal or fetal plasma, suggests that factors which control the relative concentration of each in amniotic fluid are different from those in the maternal and fetal circulations.

A New Book. **SPERMATOZOA, ANTIBODIES AND INFERTILITY.** Edited by Jack Cohen, D.Sc. and W. F. Hendry, Ch.M., F.R.C.S. Based on a recent symposium, this new volume features authoritative contributions on the accurate detection and treatment of immunological infertility. Just a few of the pertinent topics include: antibodies and sperm survival in the female genital tract ... the role of cervical mucus ... and recent advances in the diagnosis and treatment of infertility due to antisperm antibodies. March, 1979. Approx. 224 pp., 35 illus. **Price, $27.50.**

New 2nd Edition. **HUMAN REPRODUCTIVE PHYSIOLOGY.** Edited by Rodney P. Shearman, M.D., F.R.C.O.G. In its 2nd edition, this volume continues to be a comprehensive reference on reproductive physiology. Each chapter has been rewritten for increased clarity and timeliness. Internationally renowned contributors discuss cytogenetics and genetics; ovarian function and its control; carbohydrate metabolism in pregnancy; and the menopause, among other valuable subjects. Summer, 1979. Approx. 640 pp., 80 illus. **About $58.50.**

ESSENTIALS OF FAMILY PLANNING. By Josephine Barnes, D.B.E., M.A., D.M. (Oxford), F.R.C.P. (London), F.R.C.S. (England), F.R.C.O.G. This handy paperback will serve you as a short, yet comprehensive guide to current methods in family planning. Discussions cover not only family planning and birth control, but touch upon related areas such as male and female sterilization, abortion, and sexually transmitted diseases as well. 1976. 148 pp., 12 illus. **Price, $5.95.**

Faculty Opening in Obstetrics and Gynecology

The Department of Obstetrics, Gynecology and Reproductive Sciences at the University of California, San Francisco, announces the availability of a position on its full time faculty.

Rank and salary: negotiable, commensurate with training and experience.

Qualifications: M.D. with certification (or eligibility for certification) by American Board of Obstetrics and Gynecology. Demonstrated interest and ability in undergraduate and graduate education, clinical and/or basic research, and clinical practice of obstetrics and gynecology. Applicants should have a special interest in a subarea of reproductive biology.

The University of California, San Francisco is an affirmative action employer.

Start with AVC... comprehensive, economical therapy to combat vaginitis due to major vaginal pathogens* and to provide prompt onset of symptomatic relief...with the prescribing flexibility of two dosage forms.

AVC™

Cream/Suppositories

AVAILABLE ONLY ON PRESCRIPTION

Brief Summary

***INDICATIONS:** Based on a review of AVC by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: For the relief of symptoms of vulvovaginitis where isolation of the specific organism responsible (usually *Trichomonas vaginalis, Candida albicans,* or *Hemophilus vaginalis)* is not possible.

NOTE: When the offending organism is known, treatment with a specific agent known to be active against that microorganism is preferred.

"Possibly" effective: For the treatment of trichomoniasis, vulvovaginal candidiasis, and vaginitis due to *Hemophilus vaginalis* or other susceptible bacteria.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS: AVC should not be used in patients known to be sensitive to the sulfonamides.

PRECAUTIONS: As with all sulfonamides, the usual precautions apply. Patients should be observed for manifestations such as skin rash or other evidence of systemic toxicity, and if these develop, the medication should be discontinued.

ADVERSE REACTIONS: Although some absorption of sulfanilamide may occur through the vaginal mucosa, systemic manifestations attributable to this drug are infrequent. Local sensitivity reactions such as increased discomfort or a burning sensation have occasionally been reported following the use of topical sulfonamides. Treatment should be discontinued if either local or systemic manifestations of sulfonamide toxicity or sensitivity occur.

DOSAGE AND ADMINISTRATION: 1 applicatorful (about 6 g.) or 1 suppository intravaginally once or twice daily. Improvements in symptoms should occur within a few days, but treatment should be continued through one complete menstrual cycle unless a definite diagnosis is made and specific therapy initiated. If there is no response within a few days or if symptoms recur, AVC should be discontinued and another attempt made by appropriate laboratory methods to isolate the organism responsible *(Trichomonas vaginalis, Candida albicans, Hemophilus vaginalis)* and institute specific therapy. Douching with a suitable solution before insertion may be recommended for hygienic purposes. A pad may be used to prevent staining of clothing.

AVC™

Cream Each tube contains: sulfanilamide 15.0%, aminacrine hydrochloride 0.2%, allantoin 2.0%.
Suppositories Each suppository contains: sulfanilamide 1.05 g., aminacrine hydrochloride 0.014 g., allantoin 0.14 g.
*AVC has been rated "possibly" effective for these indications.

See accompanying brief summary.

1830: A decoction of columbo root and peppermint 3 or 4 times a day should be taken for the sickness to which pregnant females are commonly subject.[1]
TODAY: Clinical studies show 9 out of 10 patients with nausea and vomiting of pregnancy obtain relief in varying degree with delayed-release Bendectin tablets.[2]
In morning sickness confidence begins with
Bendectin®
Each tablet contains doxylamine succinate 10 mg., pyridoxine hydrochloride 10 mg.
trusted alternative to nausea and vomiting of pregnancy
For prescribing information see opposite page.

- Bendectin continues to be the only product indicated exclusively for morning sickness — nothing else.
- Convenient bedtime dosage.
- Works in the morning when she needs it most.

Bendectin®

AVAILABLE ONLY ON PRESCRIPTION

Brief Summary

INDICATION
Nausea and vomiting of pregnancy.

PRECAUTIONS
Because of potential drowsiness, Bendectin should be prescribed with caution for patients who must drive automobiles or operate machinery.
Studies in rats and rabbits have revealed no suggestion of drug-induced fetal abnormalities at doses of Bendectin up to 90 times the maximum human dose. In addition, several epidemiologic studies in women who received Bendectin during pregnancy have shown that the incidence of birth defects in their offspring is no higher than in women not taking the drug during pregnancy. Nevertheless, like all drugs considered for use during pregnancy, particularly during the first trimester, Bendectin should be used only when clearly needed.

ADVERSE REACTIONS
The adverse reactions that may occur are those of the individual ingredients. Doxylamine succinate may cause drowsiness, vertigo, nervousness, epigastric pain, headache, palpitation, diarrhea, disorientation, or irritability.
Pyridoxine hydrochloride is a vitamin that is generally recognized as having no adverse effects.

DOSAGE AND ADMINISTRATION
2 Bendectin tablets at bedtime. In severe cases or when nausea occurs during the day: 1 additional Bendectin tablet in the morning and another in midafternoon.

- Product Information as of January, 1978

1979 ORIENT TOURS

For Doctors Attending Tokyo, Oct. 25-31, IXth World Congress of Gynecology and Obstetrics

$544 TOTAL ROUNDTRIP AIRFARES
Los Angeles/San Francisco - Tokyo
Land services NOT necessary to qualify

Oct. 21-31: On **scheduled** jumbo jet flights of scheduled airlines at lower airfares than on known charter flights. **No land arrangements necessary.** Only 50 doctors with six or more months membership in American Medical Association or American College of Obstetrics and Gynecology, with their wives, will qualify either group of 100 eligible people for these very low airfares.

ALSO AVAILABLE

Tours combining airfares with land arrangements. Very highest quality throughout, such as deluxe and top first-class hotels, and in certain tours extensive sightseeing, dinner parties, and folklore shows to assure that you will enjoy the Orient, not just see it.

TOKYO ONLY—$899—Oct. 21-31—11 days
For doctors concentrating their time on the medical sessions in Tokyo who desire only airfares, hotel, and transfers.

JAPAN ONLY—$1099—Oct. 21-31—11 days
For doctors unable to be absent from their practices very long who want to visit the classical city of Kyoto, in addition to Tokyo.

TOKYO-HONG KONG—$1249—Oct. 23-Nov. 5—14 days
Designed to enable doctors to concentrate their professional time at the medical sessions in Tokyo and enjoy vacation time in Hong Kong.

ORIENT HILITES—$1399—Oct. 23-Nov. 7—16 days
For doctors with limited time who want significant Orient coverage. Includes the "core" of the Orient: Japan, Taiwan, Philippines, Hong Kong.

ORIENT GRAND—$1849—Oct. 23-Nov. 12—21 days
Offers the ultimate, practically all of the Far East: Japan, Taiwan, Philippines, (Bali) Indonesia, Singapore, Thailand, Hong Kong. If you have time, this is the program for you.

FETUS, PLACENTA, AND NEWBORN

Bed rest in twin pregnancy: Identification of a critical period and its cost implications

WILLIAM F. POWERS, M.D., M.P.H.
TIM C. MILLER, M.D.
Peoria, Illinois

Since twin pregnancies often result in poor perinatal outcomes, many physicians advise prolonged bed rest. Recommendations concerning the timing of bed rest conflict and are made with little assessment of costs. This review of twin pregnancies in the North Central Illinois perinatal region establishes that twins are most vulnerable if they are born between 27 and 34 weeks' gestation. If bed rest is to be imposed, it probably should be timed so as to influence this vulnerable period. Intervention (bed rest in the hospital from 27 to 34 weeks' gestation) would cost between $5,720 and $6,909 per twin pregnancy, whereas nonintervention (intensive care nursery charges for infants born before 34 weeks' completed gestation) would cost $1,689 per twin pregnancy. Before intervention can be universally advocated and costs of this magnitude incurred, a prospective controlled trial to determine the efficacy of bed rest in twin pregnancy is mandatory. (AM. J. OBSTET. GYNECOL. 134:23, 1979.)

MULTIPLE pregnancies are associated with high morbidity and mortality rates. Approximately 55 per cent of twins born in the United States weigh less than 2,500 grams at birth, and about 40 per cent of twins are born before 37 weeks' gestation. The mortality rate of twins is about four times that of singletons. In addition, twins more frequently have long-term problems such as short stature, delayed mental development, and cerebral palsy.[1] Data collected in an era of neonatal intensive care perhaps indicate a slight improvement in the prognosis for twin pregnancies,[2] but still twinning remains a very high-risk situation.[3]

From the North Central Illinois Perinatal Center, St. Francis Hospital–Medical Center, and the Department of Pediatrics, Peoria School of Medicine.

Received for publication April 17, 1978.

Accepted June 20, 1978.

Reprint requests: Dr. William F. Powers, St. Francis Hospital, 530 N.E. Glen Oak Ave., Peoria, Illinois 61637.

Since the preponderance of risks associated with twin pregnancy are related to premature delivery,[2, 4] many recommend prolonged bed rest to avoid early delivery[5–11] even though the efficacy of bed rest still remains unproved.[1, 3, 12–16] The clinician contemplating bed rest for his patient pregnant with twins unfortunately discovers no consensus as to when bed rest should be started or stopped. In fact, recommendations are contradictory. Some suggest or report starting bed rest in the hospital as early as 25 to 28 weeks' gestation[10, 13] or as late as 35 to 36 weeks' or later.[17–19] Bed rest is discontinued as early as 34 weeks' gestation[14, 20] or as late as possible.[13, 18] Thus, some suggest stopping bed rest as early as two weeks before others recommend starting.

Analysis of the recent experience with twin pregnancies in the North Central Illinois perinatal region delineates a fairly discrete "critical period" during which early delivery is associated with high morbidity and mortality rates. During this time bed rest might be

a logical intervention. The cost implications of intervention (bed rest) and nonintervention (neonatal intensive care) are also examined.

Material and methods

Patient data described in this report were gathered from two sources. First, all twin pregnancies cared for in Peoria for a four-year period from 1974 through 1977 were studied. (Triplets were not included, and higher multiples did not occur). Information was collected from delivery room records of the three hospitals providing obstetrical care, and was supplemented by state perinatal records and newborn intensive care records. Gestational age was determined from maternal dates for all infants not transferred to the Newborn Intensive Care Unit. Prolonged bed rest solely for twin pregnancy was not employed in this community during the study interval, except as noted in the discussion. Likewise, no screening programs for twins, such as routine sonography of all pregnant women, were being implemented at this time.

Second, all twin infants referred to the North Central Illinois Newborn Intensive Care Unit during this same four-year period were also included in this report. This Newborn Intensive Care Unit is part of a statewide perinatal program, and serves a region encompassing 23 counties in which approximately 18,000 live births occur annually in some 30 hospitals. Gestational age of infants admitted to the Newborn Intensive Care Unit was evaluated by the criteria of Dubowitz and associates[21] and was independently confirmed by one to three neonatologists. When gestation by maternal dates and Dubowitz criteria were discrepant by greater than two weeks, the Dubowitz estimate of gestation was used.

Hospital costs, unadjusted for inflation, were obtained from the business offices.

Results

Peoria twins. In the four-year period 218 pairs of twins were born in Peoria among 21,959 deliveries—an incidence of one in 101 deliveries. There were ten stillbirths and 28 neonatal deaths for neonatal and perinatal mortality rates of 6.6 per cent and 8.7 per cent, respectively. These compared to neonatal and perinatal mortality rates of 1.05 per cent and 1.89 per cent for all deliveries in Peoria during the same time, and thus twins accounted for 12 per cent of all neonatal deaths.

Table I lists the distribution of Peoria-born twins by gestational age. Forty-one per cent of Peoria twins were born before completing 37 weeks' gestation, and hence would classically be defined as premature. However, most of the risk of neonatal death was borne by infants of 34 weeks' gestation and less (Fig. 1). In fact, only two of the 28 neonates who died were born at 35 weeks' gestation or greater. The neonatal mortality rate for infants of 34 weeks' or less was 302.3 (26 per 86) while the rate for infants of 35 or greater weeks' gestation was 5.88 (2 per 340), a fiftyfold difference. Indeed, the neonatal mortality rate for infants of 35 or more weeks' gestation was actually half that of the entire population, although this difference is not statistically significant.

One hundred thirty-five Peoria twins (32 per cent)

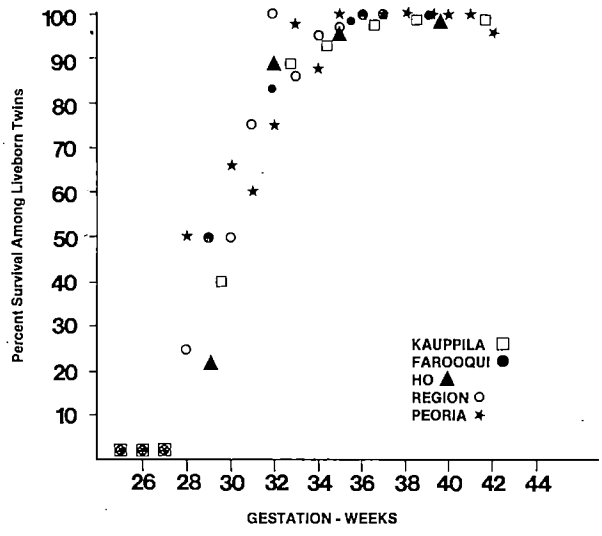

Fig. 1. Probability of survival for twins as a function of gestational age. Data of Ho and Wu,[2] Farooqui and associates,[24] and Kauppila and associates,[27] are plotted at the midpoint of the gestational age intervals they report.

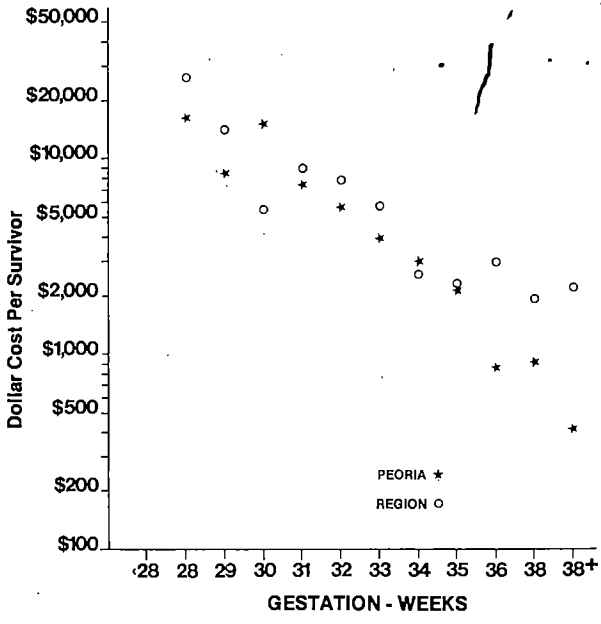

Fig. 2. Dollar cost per surviving twin as related to gestational age.

were admitted to the Newborn Intensive Care Unit and spent 2,699 days in either intensive or intermediate beds, an average of 24 days of specialized care per survivor. All Peoria-born twins of 34 weeks' gestation or less were admitted to the Neonatal Intensive Care Unit. The total intensive care bill for Peoria-born twins was approximately $440,000 or $110,000 per year. Table I also lists cost per survivor by week of gestation (total cost of care for infants of a given gestation divided by total survivors of that gestation), and Fig. 2 depicts that this cost decreases exponentially with increasing gestational age.

Regional twins. An additional 194 twin infants were referred to the Newborn Intensive Care Unit from hospitals outside Peoria. Since these infants represent only the younger and sicker members selected from a much larger, but indeterminate, population of twins, it is impossible to calculate mortality rates. Even though these data are necessarily incomplete, they are remarkably similar to the complete data gathered from Peoria babies. Thirty-six of the 37 regional neonates who died (97 per cent) were born before completion of 34 weeks' gestation. These 194 twin infants from outside Peoria required 4,458 days of intensive and intermediate care, or 28 days per survivor. Table II lists cost per survivor per week of gestation, and Fig. 2 depicts a virtually identical exponential decrease in costs with increasing gestation as was seen with the Peoria babies. The divergence noted after 35 weeks probably reflects the fact that only highly selected, very ill, infants were referred to the Intensive Care Nursery from outside Peoria.

Table III summarizes our morbidity and mortality data as related to birth before or after 34 weeks' gestation, and demonstrates the enormous risk associated with early delivery.

The magnitude of the twin problem is demonstrated by the fact that 7,157 special care days and 1.3 million dollars were expended in the care of 270 twin survivors. An average of $860 and five special care beds per day (in a nursery with an average census of 30 babies) were required to care for twins during this four-year study period.

Comment

The clinician planning bed rest for his patient pregnant with twins would probably ask at least three questions: (1) Is there a critical period when bed rest should be imposed? (2) What will it cost? and (3) Will it work? Our data suggest preliminary answers for the first two of these three questions and suggest an avenue for investigation in response to the third.

Early delivery, and its complications, is the major threat to twins.[2, 4, 5, 22–25]* These risks have most often

*Twins, of course, encounter a large number of perinatal complications.[26] Generally, however, these are fairly rare in comparison to premature delivery and its sequelae. However, late intrauterine stillbirth from presumed placental failure is of special concern. Some[13] report that this is a fairly common problem, and even advocate bed rest as a prophylactic measure late in gestation. In our series, stillbirths were rare in comparison to neonatal deaths. Hence, we do not feel that late prolonged bed rest for every twin pregnancy was warranted. Rather, it might be used in certain cases as chosen by placental function tests), hypertension, etc.

Table II. Regional twin data 1974 to 1977

been expressed as a function of birth weight. However, the obstetrician who detects twin pregnancies early and considers intervention must have risk information expressed in relation to gestational age. The Peoria data, gathered during the era of newborn intensive care, suggests that completion of 34 weeks' gestation is critical, for after this degree of maturity is attained survival is nearly 100 per cent, whereas below this degree of maturity, the mortality rate is quite high. Ninety-three per cent (26 of 28) of Peoria neonates who died were born before completion of 34 weeks' gestation. Thirty-six of the 37 regional neonates who died were also born before completion of 34 weeks' gestation. Others who report their data in relation to gestational age[2, 24, 27] also find high neonatal mortality rates in twins born very early (Fig. 1).

Others[2] have described the neonatal illnesses which constitute the morbidity experienced by twins delivered at early gestations. Hospital costs are one way to quantitate this short-term illness, and Table III shows that the hospital bill per survivor born at 34 weeks' gestation or less was ten times the bill per survivor born at 35 weeks or beyond. Thus, morbidity and mortality data point to the existence of a critical period in twin gestation which spans from "viability" to completion of 34 weeks' gestation. Therefore, in answer to the first question posed earlier, if bed rest is to be employed, it is during this time, from approximately the beginning of the twenty-seventh week until the end of the thirty-fourth week, that it appears to be a logical intervention. Conversely, little can be gained by beginning or continuing routine bed rest beyond the thirty-fourth week, for morbidity and mortality rates are already quite low.

In answer to the second question, dollar costs of bed rest are readily calculable. In late 1977, a mother pregnant with twins from outside Peoria was referred to this perinatal center for bed rest. She had had a previous cesarean section, but the current pregnancy, except for the twins, was uncomplicated. She was rested in this hospital for 6 2/7 weeks, and her bill up until the time

of delivery was $715.00 per week. The cost of her delivery and postpartum recovery are not included in this calculation. Hence, $715.00 per week approximates the current cost in this hospital of prophylactic bed rest in an otherwise healthy pregnant patient, and can be used to calculate the additional expense, over and above routine costs, which would be incurred if bed rest were routinely employed. Three calculations are made, the first assuming that bed rest is completely effective in avoiding delivery before completion of 34 weeks' gestation, the second that bed rest is completely ineffective, and the third that rest is not used at all.

Completely effective bed rest. If this intervention were entirely effective in preventing delivery prior to completion of 34 weeks' gestation, and if this rest were begun early, at the beginning of the twenty-seventh week, a total of eight weeks of hospitalization per twin pregnancy would be required. In this best case, the cost of prophylactic bed rest per twin pregnancy would be $5,720 ($715 per week times 8 weeks). Since this intervention would be completely successful, there would be no intensive care costs for babies born before 34 weeks' gestation.

Completely ineffective bed rest. If bed rest were totally ineffective in prolonging twin pregnancy, but not deleterious, the same delivery pattern as has been seen over the preceding four years would prevail. Seventy-nine per cent of pregnancies would continue to deliver after 34 weeks' gestation and would have completed the entire eight-week bed rest period. The remaining 21 per cent of deliveries would continue to occur prior to 34 weeks' gestation at a mean gestational age of 31 weeks, and these mothers would have time to complete only five of the prescribed eight weeks of bed rest. Thus, the average mother would rest for 7.3 weeks and in this worst case, the bed rest cost per twin pregnancy would be $5,220 ($715 per week times 7.3 weeks). To truly reflect the cost of this ineffective intervention, the cost of the resulting newborn intensive care would have to be included. The total cost of intensive care for Peoria infants born before 35 weeks was $368,259, and there were 218 twin pregnancies. Therefore, the cost of newborn intensive care for infants of less than 35 weeks' gestation was $1,689 per twin pregnancy. Thus, the total cost of completely ineffective prophylactic bed rest would be $6,909 per twin pregnancy.

No bed rest (nonintervention). As calculated above, the current price of nonintervention is $1,689 per twin pregnancy.

Admittedly, the estimated cost of nonintervention is low, for no value was assigned to lost lives, to family suffering induced by having a child in intensive care, or to treatment and rehabilitation of potential long-term handicaps in survivors. The upper and lower estimates of the cost of bed rest are also underestimates, for no value is assigned to the resultant family disruption, to the cost of a housekeeper or other family care arrangements, or to the cost of appropriate diagnostic procedures to detect twin pregnancies. In neither case are allowances made for physician's fees.

Even though these calculations severely underestimate true costs, they do point out that pursuing either a policy of nonintervention or intervention will be expensive. One obvious way to lower costs would be to rest in some nursing home type of setting. Certainly one should be able to find a place to rest for less than $715 per week. Some women may even rest at home. Another way to lower costs would be to employ bed rest in selected high-risk cases only.[6, 28] For instance, primigravidas pregnant with twins are known to be of higher risk.[28] In this regard, it is regrettable that many early screening tests used to detect risk pregnancies[29–31] have specifically eliminated or not clearly separated out twins.

Unfortunately, even today it is still impossible to give a valid answer to the question "will bed rest work?" There are several reasons for our ignorance concerning this intervention. First, the early diagnosis of twin pregnancies has historically been a problem.[1] However, when a community makes a concerted effort with ultrasound to diagnose twins early, there can be much improvement.[32] Hormonal screening may be of additional help[32, 33] although further clarification is needed.[34, 35] Also, real-time ultrasound has enormous potential in the early diagnosis of twin pregnancies. Thus, the traditional problem of early diagnosis is solvable, although the technology available today requires wider application.

Second, a great part of the confusion concerning the efficacy of bed rest in twin pregnancy is due to the erratic way in which bed rest has formerly been used. Waiting until 36 weeks to start bed rest or continuing bed rest as late as possible[3, 17, 18] is imposing this presumed prophylactic measure far too late, well after the period of greatest risk. Similarly, beginning bed rest at 30 or 32 weeks' gestation, as is commonly practiced,[3, 15, 36–38] is again starting too late, for a large portion of the morbidity and mortality due to premature delivery occurs in infants born before this period. Not surprisingly, when bed rest is imposed at inappropriate times, evaluation of efficacy is difficult.

Third, all reports on the efficacy of bed rest are retrospective reviews and generally do not eliminate patient selection bias [i.e., a patient whose uterus was larger would be more likely to be diagnosed as a twin

pregnancy at a given gestational age, and hence rested. If larger twins resulted, was it because of the bed rest or because they were bigger to begin with? Similarly, "low-risk women" (i.e. more affluent, more health conscious) would be more likely to heed the bed rest advice. If larger twins resulted, was it because of the bed rest, or of the inherent characteristics of the mother?][1] More recent reviews on this subject still do not clarify this issue.[3, 12–16, 28]

Answering the question of the efficacy of bed rest is becoming increasingly important. Already in the reported English literature, a minimum of 88 women years of bed rest has been expended on healthy mothers solely to prolong their twin pregnancies, and still its efficacy is unproved (references available upon request). Certainly, the unreported world experience is far greater. As new technology facilitates early diagnosis of twin pregnancy, more women will undoubtedly be rested in an uncontrolled and erratic fashion, even though this intervention is of unproved benefit. Also, as more perinatal programs are implemented in the United States, and more maternal and child health funds become available,[39] these limited funds could be squandered on unproved interventions in twin pregnancies.

Hence, it becomes essential that this perinatal intervention be well evaluated at the present time. Certainly there is precedent in the United States for prospective controlled evaluation of perinatal interventions.[40] Further, there is vast experience in perinatal medicine with unfavorable results that arise from widespread application of so-called "logical" but unproved perinatal interventions. Hence, a prospective controlled trial of prolonged bed rest to improve the outcome of twin pregnancy is in order. In this study, bed rest should be applied so as to coincide with the critical period of early delivery, i.e., 27 to 34 weeks. An important end point in planning and evaluating this trial should be the prolongation of twin pregnancies beyond 34 weeks' gestation in women who rest.

The value of diagnostic ultrasound as a screening test for intrauterine growth retardation: Comparison of nine parameters

B. K. WITTMANN
H. P. ROBINSON
T. AITCHISON
J. E. E. FLEMING
Vancouver, British Columbia, Canada, and Glasgow, Scotland

In an attempt to devise a screening method for the detection of unsuspected IUGR, a battery of ultrasonic measurements of the fetus were performed in a series of 255 patients at approximately 32, 34, and 36 weeks. The results obtained from the 16 growth-retarded and the 239 normally grown babies were evaluated. While no single measurement was found to discriminate the two groups, a simple combination of crown-rump length times area of trunk allowed us to identify an at-risk group comprising 11 per cent of the population. The false positive and false negative results were acceptable at levels of 10 and 6 per cent, approximately. It is considered that these results would justify a larger and prospectively randomized controlled trial to assess the benefits and drawbacks of applying these measurements in a screening schedule. (AM. J. OBSTET. GYNECOL. 134:30, 1979.)

THE COMPLICATIONS associated with intrauterine growth retardation (IUGR) are well known. However, the recognition of this problem before birth in an average obstetric population is less than satisfactory. In 1975, at the Queen Mother's Hospital in Glasgow, only 38 per cent of babies with birth weights below Lubchenco's tenth percentile[1] were recognized during the antenatal period. To achieve even this low detection rate almost five times as many pregnancies were monitored for anticipated or suspected growth retardation. Similar unsatisfactory results have been reported by Tejani, Mann, and Weiss[2] and Campbell.[3]

Among the diagnostic aids used in the antenatal monitoring of potentially growth retarded fetuses, diagnostic ultrasound has been shown to be of value in making a positive diagnosis. A number of authors have described their results, either by using serial ultrasonic measurements of the fetal biparietal diameter (BPD) to detect abnormal growth patterns or by a single measurement, to estimate weight and to screen for IUGR.[3-11] While serial cephalometry frequently permits identification of a growth-retarded fetus, this technique is impractical logistically for screening the total obstetric population, where the incidence of IUGR is approximately 5 per cent. The use of a single BPD measurement is equally unsatisfactory as a screening test as its sensitivity is only in the region of 50 per cent.[7-9]

A number of other measurements have been studied, including diameters and circumferences of the trunk,[10-17] hourly fetal urine production rates (HFUPR),[18] and total intrauterine volume (TIUV).[19] Trunk measurements alone have not been shown to reliably separate growth-retarded from normal pregnancies, although in combination with head measurements and used in form of a ratio reasonable separation has been achieved at or near term.[3, 20, 23] A low HFUPR would appear to identify well a growth-retarded fetus, but in the clinical setting the technique is impractical for routine use. Gohari, Berkowitz, and Hobbins[19] in their study of TIUV reported values below the first standard deviation line of their nomo-

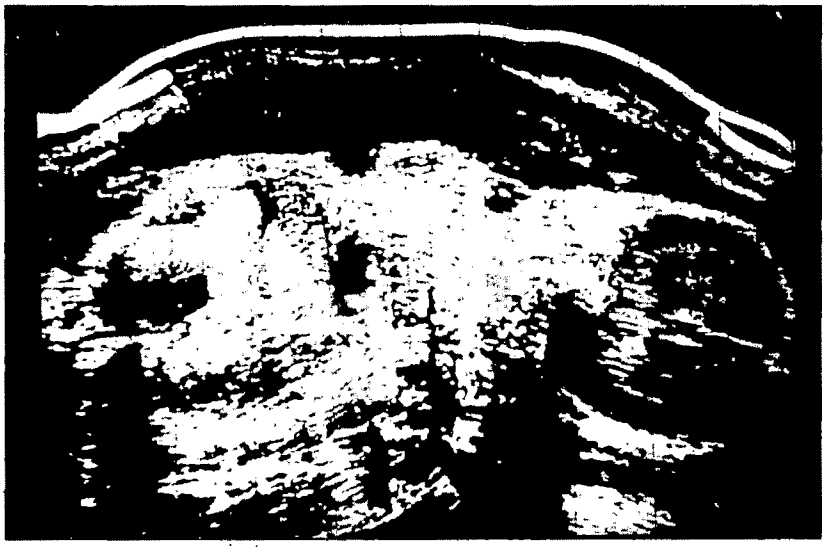

Fig. 1. Crown-rump length, 32 weeks' gestation.

gram in all 28 of the 96 "at risk" pregnancies studied which resulted in the birth of a growth-retarded fetus. There were, however, 15 of the remaining 68 normal cases in the range of −1 to −1.5 standard deviations. The authors considered that the technique was a relatively simple one and that in practice the TIUV was a good predictor of IUGR.

In designing this study, we concentrated entirely on measurements of the fetus, this being the ultimate "object" of interest. It was the aim of the study to identify which measurement or combination of measurements would best discriminate the growth-retarded from the normally grown fetus, and to determine at which gestational age the smallest number of false positive and false negative results would be incurred.

Patients and methods

A total of 255 women were selected for the study, the only criterion for admission being reliable dating of the pregnancy. The age of the pregnancy was assessed by accurate documentation of a normal menstrual cycle and last menstrual period, confirmed by an early bimanual examination of the uterus and, in over 50 per cent of patients, by an ultrasonic examination before 20 weeks.

Three ultrasonic examinations at approximately 32, 34, and 36 weeks were performed and on each occasion nine measurements were made (Table I). The equipment used was a Nuclear Enterprise Diasonograph, NE 4102, with a 2.5 MHz transducer.

A slightly modified version of Campbell's[21] combined B− and A−scan method of cephalometry was employed for the BPD measurements, with the electronic calipers calibrated to an assumed tissue velocity of 1,600 M. per second. All other measurements were performed by direct measurement from Polaroid photographs of the appropriate sections recorded on a storage oscilloscope (assumed tissue velocity of 1,540 M. per second), and corrected to life size. A standard map measurer was used for the circumference measurements and a HAF planimeter No. 315 for the area measurements.

Table I. Nine fetal parameters

Biparietal diameter (BPD)
Occipitofrontal diameter (OFD)
Head circumference (HC)
Head area (HA)
Anteroposterior trunk diameter (APTD)
Transverse trunk diameter (TTD)
Trunk circumference (TC)
Trunk area (TA)
Crown-rump length (CRL)

The crown-rump length (CRL) was measured from a section which showed both the fetal bladder and the midline of the fetal head (Fig. 1). Measurements of the occipitofrontal diameter (OFD), the circumference (HC), and the area (HA) of the fetal head were taken from elliptical sections which showed a midline echo and a short double echo one third of the way along the midline (Fig. 2).[20] The trunk measurements were obtained from a transverse section of the upper abdomen of the fetus at the level of the umbilical vein (Fig. 3). Apart from the BPD measurement, which was immediately available, the remainder of the measurements were performed without knowledge of the pre-

Fig. 2. Skull section, 32 weeks' gestation.

vious history or eventual outcome of the pregnancy.

At delivery, a diagnosis of growth retardation was made by reference to the tenth centile line on Lubchenco's weight for gestation nomogram.[1] (In the Queen Mother's Hospital only five per cent of the babies have weights at birth which fall below this line.) The gestational ages of the infants were confirmed by pediatric assessment.

All patient information, including clinical and measurement data and outcome, was then subjected to computer analysis.

Single measurements. Sixteen of the 255 babies (6.3 per cent) were found to be growth retarded[1] at delivery. For the purpose of this study, each of the three sets of measurements was used in compiling the results.

Nomograms comprising the ninetieth, fiftieth, and tenth centile lines, covering the period of study (31 to 37 weeks), were constructed from all of the measurement data for each of the nine individual parameters. The distribution of the measurements obtained from the fetuses with IUGR at delivery was then evaluated.

In this study no single parameter reliably separated the normal from the growth-retarded fetuses. With the tenth centile lines used as the dividing point, the false negative results (i.e., the percentage of results from growth-retarded fetuses found to be lying above the line) for BPD, TA, and CRL were 56, 29, and 60 per cent, respectively (Figs. 4, 5 and 6). Similar results were obtained for the other head and trunk measurements.

Combination of two measurements. The results obtained by combining two of the parameters in various ways were next examined. The best combination was found to be the product of TA and CRL (Fig. 7), with an over-all false negative rate of 33 per cent. While this rate is higher than that achieved with the "trunk area" alone, perusal of the graphs (Figs. 5 and 7) reveals that with the TA times CRL combination there were fewer false results, both negative and positive, after 235 days (33+ weeks), all but two being found in the earlier weeks. The false positive rate (the percentage of results from normally grown fetuses lying below the tenth centile line) remained fairly constant throughout the period at just under 6 per cent. In absolute figures there were 38 results below the tenth centile line after 33½ weeks, of which 14 (45 per cent) were derived from growth-retarded fetuses. These 38 data points constituted 11 per cent of all results during this period. This combination proved superior to either TTD × CRL, or TC × CRL.

Combinations providing ratios of head to trunk measurements were also examined. Of these the best was the ratio of the respective areas with a false negative rate of almost 50 per cent and an even dispersion of false results throughout the period of study.

Multiple measurements. A number of more complex computations involving three or more individual measurements were performed. The formulation giving the best separation of normal and growth-retarded fetuses was one in which HA × BPD was plotted against TA × (CRL-BPD). When individual graphs were compiled for each week of the study period (32 to 37 weeks) and the data analyzed, a very low rate of false negative results (1/45) was found (Table II), together with a rate of false positive results which fell to a reasonable level (<5 per cent) from 34 weeks onwards. The discriminatory lines for each week are shown in Fig. 8. A value falling below the appropriate line would indicate that the fetus is likely to be growth retarded.

Comment

In view of the poor antenatal detection rate of IUGR by clinical methods and the fact that such babies are at greater risk of perinatal death, neonatal morbidity, and long-term physical and mental handicap than normally grown babies, a reliable screening test would be extremely useful. To be practical, however, such a screening test should be simple, acceptable to the patient and her physician, and cost effective. It should also have a high degree of sensitivity with a low incidence of false results.

In this study a battery of fetal measurements have been evaluated both singly and in various combinations. While no single measurement was reliable in the context of a screening test, the simple combination of TA × CRL was found to separate the results from the normal and growth-retarded pregnancies after 33+ weeks with a low incidence of false negative and false

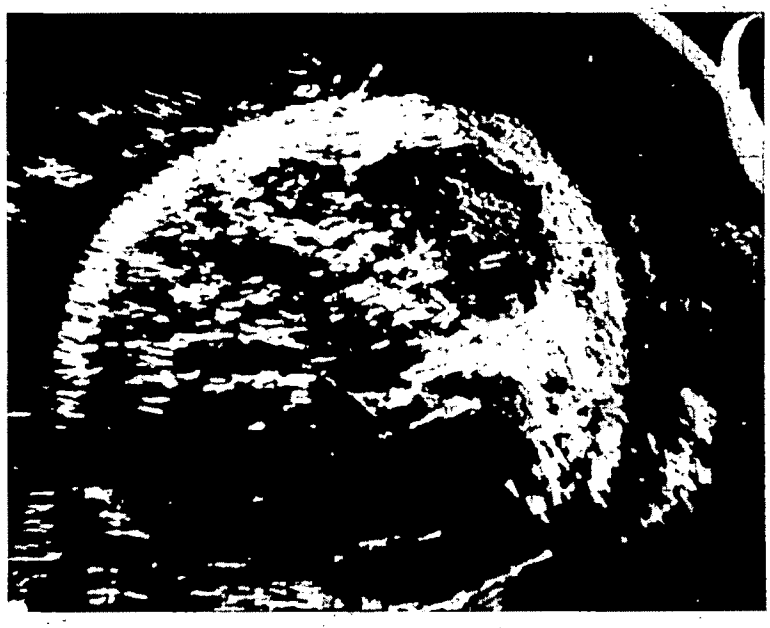

Fig. 3. Trunk section, 32 weeks' gestation.

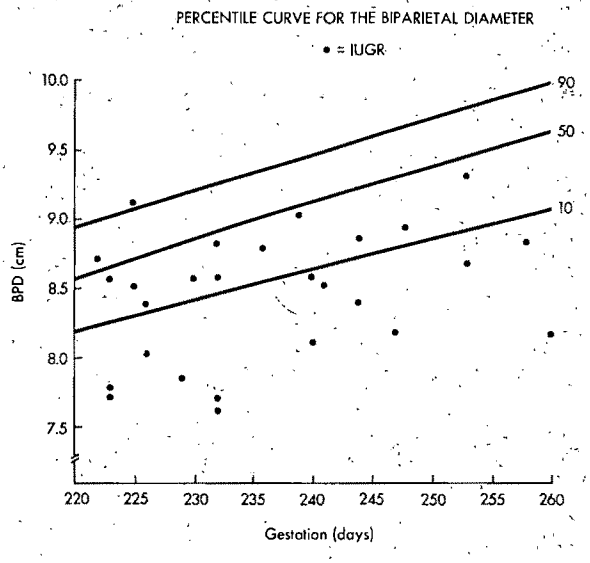

Fig. 4. Percentile curve for the biparietal diameter. Distribution of the results from fetuses born with growth retardation.

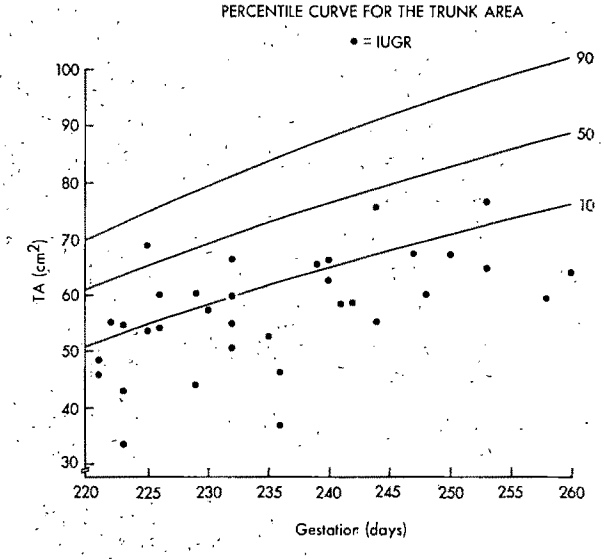

Fig. 5. Percentile curve for the trunk area. Distribution of the results from fetuses born with growth retardation.

positive findings. In numerical terms, this combination allowed us to identify an "at risk" group, which comprised 11 per cent of the population with almost one half (45 per cent) of this 11 per cent being true positive results. In addition it missed only 10 per cent of the results from growth-retarded fetuses, with an over-all false positive rate of approximately 6 per cent.

With the more complex system where a value related to head volume (head area × BPD) is plotted against a value related to trunk volume [trunk area × (CRL − BPD)], slightly lower rates of false results were achieved. While this system is inherently less attractive because of the greater number of measurements involved, it has certain merit in that it incorporates a ratio of head "size" to body "size," a parameter which is often abnormal in growth-retarded fetuses. Furthermore, the measurements more closely approximate to the fetal volume and therefore fetal weight.

While we appreciate that the numbers involved in this study are small, these findings are encouraging, with a pick-up rate of growth-retarded fetuses much in excess of that achieved by routine clinical means, and

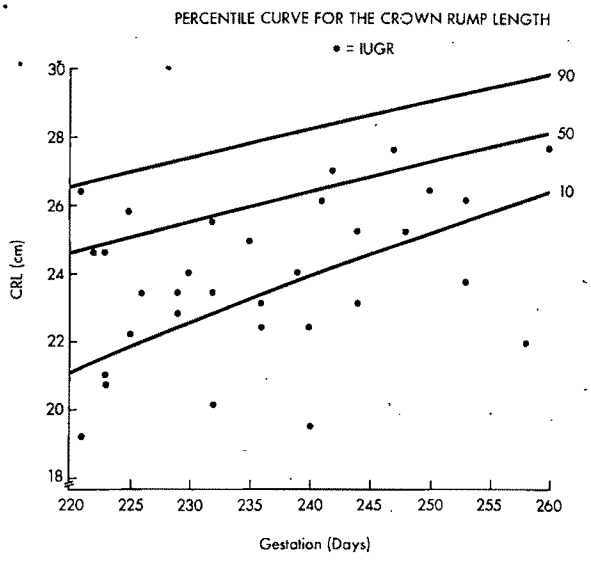

Fig. 6. Percentile curve for the crown-rump length. Distribution of the results from fetuses born with growth retardation.

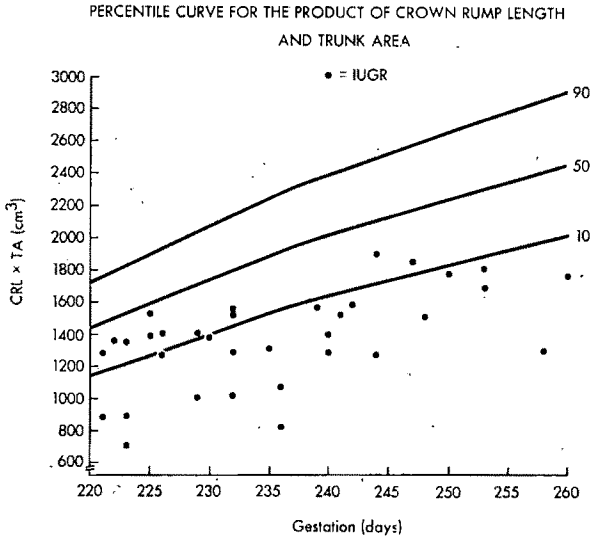

Fig. 7. Percentile curve for the product of crown-rump length and trunk area. Distribution of the results from fetuses born with growth retardation.

with a rate of false results which would be tolerable logistically.

In our experience and with the equipment used in this study, the sections required for the complete set of measurements may be obtained with little difficulty and on average require less than 10 minutes per patient. However, the map measurer and planimeter are awkward to use and are potentially inaccurate, especially when photographs of scan converter images are used.[22] To overcome these problems, Fleming and associates[22] designed an electronic measuring device which allows measurements to be made directly from the gray-scale display. With this instrument, area and perimeter measurements can be obtained rapidly and with a high degree of accuracy. As a result, it is considered that a large-scale screening program is now practicable. Before advocating the more widespread application of such a program, however, answers should be sought to the following questions. (1) Would the investment in resources and manpower be justified in terms of improved perinatal mortality and morbidity rates? (2) Would iatrogenic morbidity be increased as a result of inappropriate decisions being taken in the false positive and false negative groups? We plan to approach these problems by conducting a prospective randomized controlled trial.

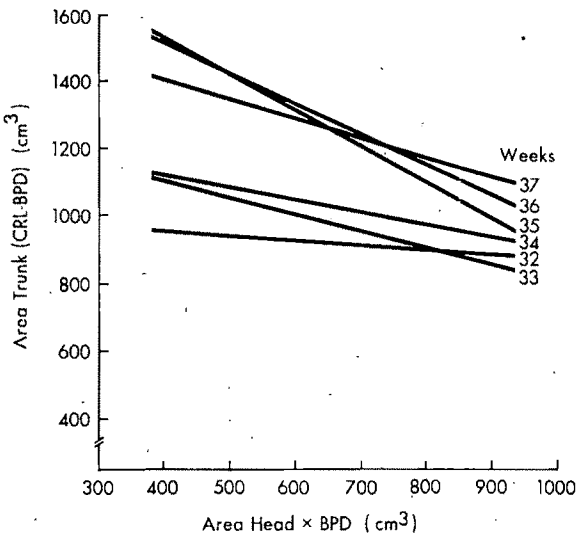

Fig. 8. Discriminatory lines from 32 to 37 weeks' gestation in the identification of fetuses born with growth retardation. HA × BPD is plotted against TA × (CRL − BPD).

Table II. False positive and false negative results in the identification of fetuses born with growth retardation*

Week of gestation	No. of results			
	Normal	Growth retarded	False positive	False negative
32	104	9	21 (20%)	—
33	100	10	11 (11%)	—
34	112	10	5 (4%)	1
35	108	7	5 (5%)	—
36	91	5	1 (1%)	—
37	45	4	—	—

*HA × BPD is plotted against TA × (CRL-BPD).

We would like to express our gratitude to Prof. Ian Donald and the staff of the Queen Mother's Hospital, Glasgow, for their help and encouragement and to the British and Canadian Medical Research Council for supporting this work.

Fetal heart rate acceleration in labor: Excellent prognostic indicator

O. HENDERSON POWELL, M.D.
ARLENE MELVILLE, R.N.
JARLATH MACKENNA, M.D., F.A.C.O.G.
Norfolk, Virginia

This study explores the significance of fetal heart rate acceleration in labor. Fetal heart rate accelerations were studied in 1,677 monitored laboring patients. Fetal outcome was analyzed according to perinatal mortality rate, Apgar scores, and incidence of late deceleration. The presence of accelerations of the fetal heart rate during labor proved to be an excellent indicator of subsequent good fetal outcome. (AM. J. OBSTET. GYNECOL. 134:36, 1979.)

SINCE the early sixties the role of electronic monitoring in the management of labor has assumed increasing importance. The initial three basic patterns described by Caldeyro-Barcia and colleagues[1] and Hon[2] have been refined so that now a great number of patterns can be identified and closely associated with variants in fetal condition. In this study an extension of the work of Rochard in France and Schifrin in this country[3] was carried from the antepartum period into labor. They have originally described the usefulness of antepartum nonstress testing with good subsequent fetal outcome. In this study we have attempted to correlate fetal heart rate acceleration in labor with a similar prognosis.

Materials and methods

During the 12 months from January 1, 1976, to December 31, 1976, 2,265 infants were delivered at DePaul Hospital, which is one of the teaching hospitals of the Eastern Virginia Medical School. Of these patients, 1,677 (74 per cent) were monitored electronically by means of standard Corometrics 111B monitors.* Internal monitoring by means of a scalp electrode was utilized in 1,276 patients. Intrauterine catheter was used in 848 patients. The remainder were monitored externally with Toco transducers and external ultrasound technique. Since the staff and residents have an agreed policy of total monitoring, the only reasons for not monitoring patients were precipitous labor, lack of availability of a monitor, or elective cesarean section.

The patients were drawn from both the private and clinic segments of the obstetric population in the ratio of 65 per cent private to 35 per cent clinic. It was, therefore, felt that this represented a cross-section of an average obstetric population.

Classification of recognized fetal heart rate and uterine contractility changes follow the standard classification of Hon.[2] An acceleration was defined as an increase of fetal heart rate of 15 beats per minute above the normal baseline occurring with a contraction. Three accelerations occurring in a 15 minute period were necessary for inclusion in the acceleration category. Only uniform fetal heart rate acceleration patterns are included. Those accelerations occurring in association with decelerations or representing rebound phenomena were excluded from this study.

Results

The results of this study are detailed in Table I. The perinatal mortality rate for all patients delivered at DePaul Hospital in 1976 was 18.6 per thousand. The perinatal mortality rate for that group of monitored patients was 14.9 per thousand. Fetal heart rate accelerations were present in 953 of those patients monitored (56.8 per cent) while no accelerations were observed in 724 patients (43.2 per cent). It is important to note the marked decrease in the perinatal mortality

Table I. Perinatal data

Category	*Number percentage*	*Late decelerations*	*5 Minute Apgar < 7*	*Perinatal mortality rate*
Total deliveries	2,265/100%	—	57/2.5%	18.6/1,000 (42 deaths)
Monitored	1,677/74%	87/5.2%	34/2.0%	14.9/1,000 (24 deaths)
Nonmonitored	588/26%	—	23/3.9%	27.2/1,000 (18 deaths)
Accelerations present	953/56.8%	11/1.15%*	8/0.84%*	4.2/1,000* (4 deaths)
Accelerations absent	724/43.2%	76/10.49%*	76/10.49%*	27.5/1,000* (20 deaths)

*$P < 0.01$.

rate of those patients who exhibited fetal heart rate accelerations in labor. Only four patients showing this fetal heart rate change died, giving this group of patients the the excellent perinatal mortality rate of 4.2 per thousand. These four deaths were due to beta streptococcus pneumonia in a term infant, intracranial hemorrhage in a 37 week gestation infant delivered by midforceps, and respiratory distress syndrome in two preterm infants. The group of patients that did not show accelerations in labor had a much higher perinatal mortality rate of 27.5 per thousand, 20 deaths having occurred in this group. In evaluating these 20, it was found that conditions often associated with hypoxia (i.e. diabetes, postmaturity, sepsis, pre-eclampsia) were readily demonstrable in 16 patients. One may conjecture that the loss of accelerations in these infants can be related to the underlying pathophysiology of the fetal-placental unit, especially in cases where obvious causes of placental dysfunction can be demonstrated. Obvious explanations, however, are not available for all of these patients as two pre-term infants died of respiratory distress syndrome and two died from congenital anomalies.

The improved outcome of neonates who showed intrapartum fetal heart rate accelerations is likewise demonstrated by observing the incidence of low Apgar scores and late decelerations in the varied groups studied. Five-minute Apgar scores of less than 7 occurred in only eight patients (0.84 per cent) with acceleration patterns present, while 26 patients (3.9 per cent) without accelerations had 5 minute Apgar scores of less than 7. The difference in the occurrence of late decelerations between the two groups is likewise striking. Only 11 patients (1.15 per cent) with accelerations exhibited late decelerations while 76 patients (10.49 per cent) without accelerations had late decelerations (Table I).

The significance of the values of each of these three subgroups was evaluated with a chi square technique, and differences for all three groups were found to be significant to a probability factor of less than 0.01.

While no differentiation was made between vertex and nonvertex presentations when statistics were computed, breech presentations were examined separately. Of the 91 breech presentation infants delivered in this series, 76 were monitored. Only two of these failed to show accelerations in labor. There was one death among the breech deliveries. It occurred secondary to severe hypoxia in a vaginal delivery. Interestingly, accelerations were not present during labor.

Comment

Rochard and associates[3] have shown that fetal heart rate accelerations in response to fetal movement in the nonlaboring patient correlate well with fetal well-being and that this correlation can be used as a basis for a useful antepartum test. This assumption is based on the fact that fetal heart rate accelerations in response to movement are indicative of an intact and well-oxygenated central nervous system and secondary appropriate cardiac response.

The benign aspects of a reactive acceleration pattern have been amply demonstrated in every study in which this sign has been looked for. In analyzing baseline recordings of fetal heart rate and uterine activity, both Schifrin[4] and Trierweiler and colleagues[5] have shown that the presence of increased accelerations virtually precludes the development of late decelerations in the subsequent stress of induced contractions. While the absence of accelerations has been shown to carry a much more ominous prognosis, it is not as accurate a predictor of poor outcome as accelerations with movement are of good outcome.[6] It would appear that our data substantiate the premise that a fetus with an intact neurocardiac system as demonstrated by accelerations in labor has sufficient reserve in terms of levels of oxygenation and placental reserve to well tolerate the rigors of labor. Our data suggest that, just as they do in

the antepartum period, fetal heart accelerations lend reassurance in the intrapartum situation that the fetus who is healthy and shows the proper response to the stress of contractions, as demonstrated by accelerations, has an excellent likelihood of tolerating labor and delivery without difficulty. While the absence of fetal heart rate accelerations is not as accurate a predictor of fetal distress, this lack of acceleration can, nonetheless, alert the obstetrician to be especially judicious in the use of procedures which may stress the fetus further. If accelerations are present, one can be confidently reassured, often very early in the labor period, that the chances of good fetal outcome are excellent. However, if accelerations are not present, one should observe the patient even more closely, being careful to assure adequate hydration, avoiding the supine position, using analgesia and anesthesia with care, and being alert for signs of fetal distress.

Demonstration of immunoreactive somatostatin-like substance in villi and decidua in early pregnancy

With the use of the radioimmunoassay for growth hormone–releasing inhibiting factor (GIF), it was found that measurable amounts of GIF-like substance existed in the chorionic villi and decidua of pregnant women. The indirect immunofluorescent method revealed that the higher intensity of GIF-like immunofluorescence was presented in cytotrophoblasts rather than in syncytiotrophoblasts of the villi and in stromal cells of the decidua. (AM. J. OBSTET. GYNECOL. 134:39, 1979.)

SINCE ARIMURA and associates[1] reported the method for the measurement of somatostatin (growth hormone–releasing inhibiting factor [GIF]) by radioimmunoassay (RIA), the existence of GIF-like substance has been demonstrated in various organs and tissues by both the RIA and immunohistochemical methods. Dubois, Paulin, and Assan[2] found, after using the immunohistochemical method, that the GIF-like substance localized in the descrete cells of the Langerhans islets of the pancreas in addition to the hypothalamus. Such a wide distribution of GIF-like substance may lead to the concept that GIF is not a systemic but a local hormone. In the placenta, little is known as to whether or not the release of placental hormones is under the control of some local hormones. However, it may be reasonable to assume that some unknown local hormones participate in the regulation of known hormonal activities during pregnancy. In this study, we attempted to demonstrate the existence of GIF-like substance in villous and decidual cells in early gestation with the RIA for GIF and the immunofluorescent technique of Barry, Dubois, and Carette.[3]

Material and methods

The antiserum of GIF was prepared by immunizing rabbits with synthetic somatostatin conjugated to bovine serum albumin (BSA) with glutaraldehyde. The ratio of somatostatin and BSA was 1:4. The complex antigen obtained was emulsified with complete Freund's adjuvant. The emulsion was injected as multiple intradermal injections on the shaven backs of the rabbits. This antiserum was tested by the RIA and the precipitation method, by agar. The antiserum of human chorionic gonadotropin (HCG) was offered from Mochida

0002-9378/79/090039+06$00.60/0 © 1979 The C. V. Mosby Co.

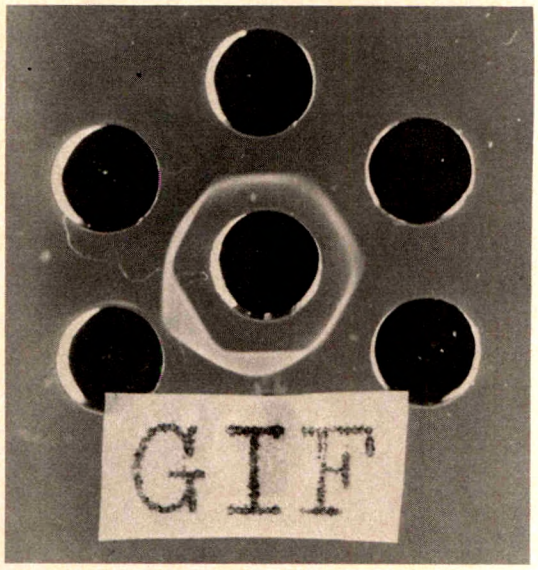

Fig. 1. Microimmunodiffusion pattern of GIF. A precipitin band is seen between the antigen *(outside)* and antibody wells *(central)*.

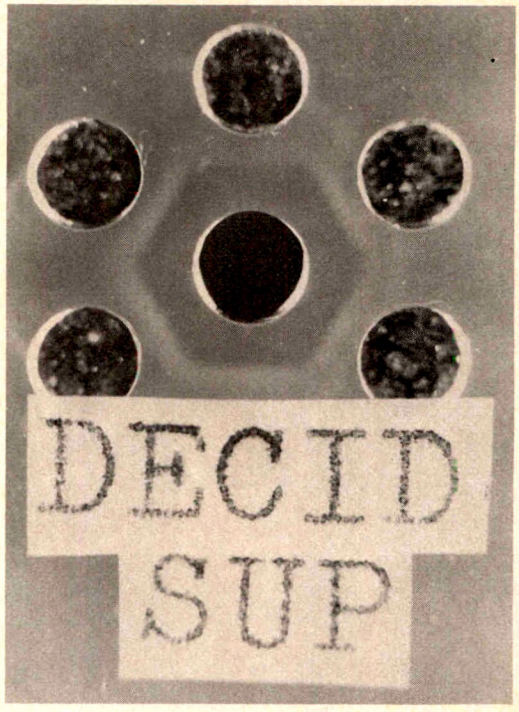

Fig. 2. Microimmunodiffusion pattern of the decidual extract. A precipitin band is seen between the wells of extract *(outside)* and of antibody *(central)*.

Pharmaceutical Company (Tokyo, Japan). A total of 0.10 ml. of the anti-hCG serum at a dilution ratio of 1:1,000,000 could neutralize 1.0 mI.U. of hCG.

Immunodiffusion test. The micro–multiple diffusion test was performed by the method of Crowle.[4] The slide glass was coated with agar* dissolved in 0.15M sodium chloride and 0.05M phosphate buffer (pH 7.2) containing 0.1 per cent sodium azide, and solidified. The wells were punched in the agar layer with a capillary glass tube and charged with the reactant and antibody.

Radioiodination and RIA of GIF. One microgram of (Tyr^8)-GIF, 100 ng. per 2 μl of lactoperoxidase,† and 10 μl of 0.05M ammonium acetate buffer, pH 5.0 (A.A.B.), were added to 500 μCi of ^{125}I-sodium.‡ The reaction was started by adding 2 μl (204 ng.) of hydrogen peroxide (diluted 1:5,000 with deionized water). After 5 minutes the reaction was terminated by diluting with 1 ml. of 0.002M ice-cold A.A.B., pH 4.6. The reaction mixture was immediately applied on a carboxymethylcellulose column (1 by 8 cm.) equilibrated with 0.002M A.A.B. and then with 0.2M A.A.B. at 4° C. The tubes containing ^{125}I-(Tyr^8)-GIF were stored at −20° C. until used.

All dilutions were made with standard diluent consisting of 0.1 per cent gelatin, 0.025M ethylenediaminetetraacetate 0.15M sodium chloride, and 0.01M phosphate buffer, pH 7.5 (GPBS). A total of 100 μl of a known amount of GIF or sample solution was added to a mixture of 200 μl of GPBS and 100 μl of anti-GIF serum with a final dilution of 1:2,500. This concentration of anti-serum was sufficient to bind 25 to 40 per cent of ^{125}I-(Tyr^8)-GIF in the absence of unlabeled GIF. Then 100 μl of ^{125}I-(Tyr^8)-GIF was added. The tubes were incubated for 24 hours at 4° C. After incubation, 500 μl of dextran-coated charcoal solution was added, and the tubes were incubated for an additional 15 minutes at 4° C. Finally, the tubes were centrifuged at 3,000 r.p.m. for 30 minutes and the supernatant was decanted. The precipitate was counted with a well-type counter. All samples were assayed in duplicate. The detailed procedure for GIF-RIA will appear elsewhere.*

Extraction procedure of GIF-like substance from villi and decidua. Human villous and decidual tissues were obtained from cases of spontaneous and legal abortion at 5 to 12 gestational weeks. The material was collected in a tubes containing 0.5 ml. of Trasylol (10,000 K.I.U. Bayer, West Germany), homogenized with 5 ml. of 2N acetic acid at 0° C., and centrifuged at

3,000 r.p.m. for 30 minutes. The supernatant was lyophilized. The extract was dissolved with GPBS when assayed.

Immunofluorescence. The chorionic villi and decidua were obtained from pregnant women at 6 to 8 gestational weeks by legal abortion. These tissues were immediately washed with ice-cold 0.15M saline in order to remove blood. After fixation for 2 to 3 days in Bouin's-Holland's fluid, the tissues were carefully washed with 0.1M phosphate buffer, pH 7.8, dehydrated by ethanol, and embeded in paraffin. The tissues were sliced at 10 μm thickness with a microtome and the sections were treated with the indirect immunofluorescence technique on a slide glass. Namely, the sections were treated with rabbit anti-GIF serum (dilution ratio 1:20) for 50 min. at room temperature, and immersed in anti-IgG with fluorescein isothiocyanate (1:5 dilution) for 50 min. Then the preparations were washed three times with 0.1M phosphate buffer for 5 min. and finally fixed with 0.5 per cent aqueous gelatin. The other preparations were treated with either GIF-absorbed anti-GIF serum or normal rabbit serum as the control tests. The reaction was studied with an Olympus fluorescence microscope.*

Results

Immunodiffusion test. The precipitin band formed a circular fusion between the wells of GIF and of anti-GIF serum. According to Crowle,[4] this coalescence of the proximal band tips signified a reaction of identity (Fig. 1). This pattern of GIF reaction similarly was seen in decidual immunodiffusion as shown in Fig. 2.

*Olympus Optical Ltd., Tokyo, Japan

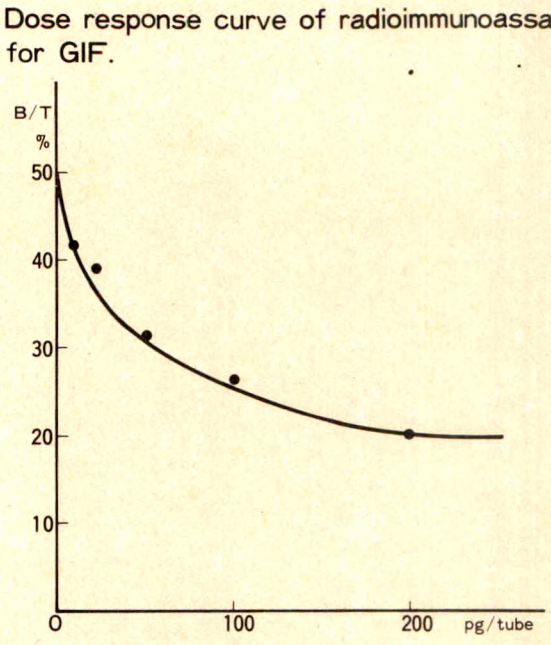

Fig. 3. Standard curve for the radioimmunoassay of GIF. The intra-assay and interassay variances were 6.1 and 12.4 per cent, respectively.

RIA of GIF. The standard curve of GIF was shown in Fig. 3. As little as 3.9 pg. per tube of synthetic GIF was detected in this assay system. No significant competition was observed between synthetic GIF and other peptide hormones tested (oxytocin, vasopressin, thyroid stimulating hormone–releasing hormone (TRH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin, growth hormone (GH), adrenocorticotropic hormone (ACTH), and hCG, except luteinizing hormone releasing factor (LHRF) which slightly cross-reacted with anti-GIF at the dose of 10 μg (Fig. 4). The displacement curves of the extracts from both villi and decidua were parallel with that of standard GIF (Fig. 4).

As shown in Table I, GIF-like immunoreactivity was detected in the villi in five of six normal pregnant women and in four of seven women who had abortions. Such immunoreactivity was found in all decidua obtained from both normal women and those who had abortions.

Immunofluorescence. The immunoreactive cells were located along the syncytial layer of chorionic villi, but the intensity of immunofluorescence in the cytotrophoblast was higher than that in the syncytiotrophoblast. The immunofluorescence was not visible in the stromal cells of the villi (Fig. 5). The immunoreactivity was not visible in chorionic villi treated with normal rabbit serum (Fig. 6).

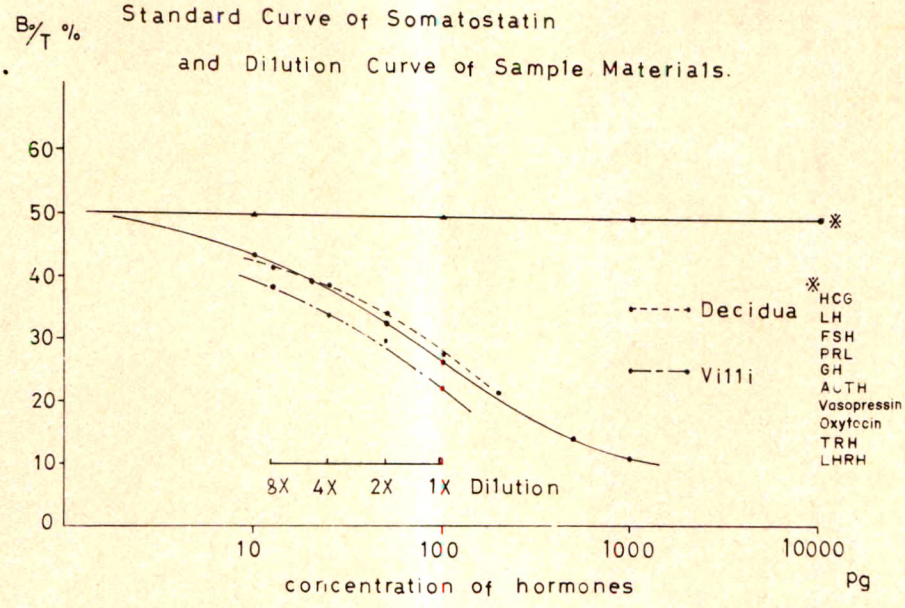

Fig. 4. Cross-reaction of peptide hormones and villous and decidual extracts.

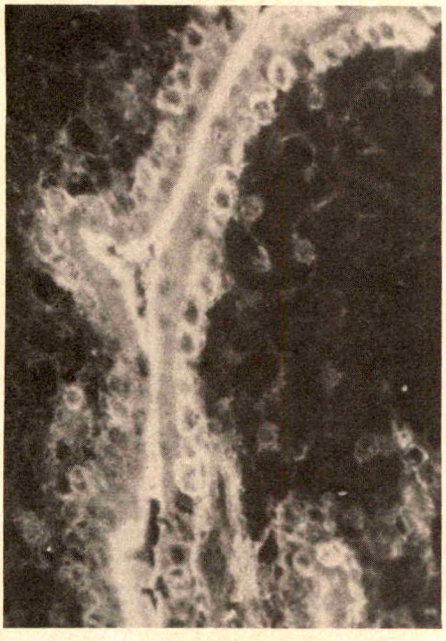

Fig. 5. GIF immunoreactive cells are present in cytotrophoblasts rather than in syncytiotrophoblasts (7 weeks' gestation).

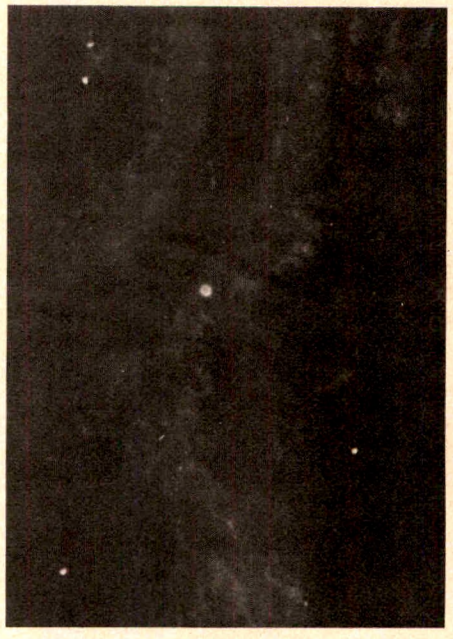

Fig. 6. Villous tissue of 7 weeks' gestation after an application of normal rabbit serum. No immunoreactive cells are seen.

On the other hand, the decidual stromal cells also reacted to the immunofluorescence, while such a reactivity was not observed in the epithelium of the endometrial glands (Fig. 7). The immunofluorescence was not seen when the tissues were treated with normal rabbit serum (Fig. 8). These findings differed from those of immunofluorescence with hCG; the hCG immunoreactive cells were located in the syncytiotrophoblasts rather than in the cytotrophoblasts, and immunofluorescence was not found in the control specimen treated with normal rabbit serum (Figs. 9 and 10).

Comment

The existence of immunoreactive GIF has been demonstrated in the hypothalamus and brain of the human fetus between 10 and 20 weeks' gestation.[5] In

Fig. 7. GIF immunoreactive cells seen in the decidual stroma of 7 weeks' gestation.

Fig. 9. hCG-immunoreactive cells seen in both the cytotrophoblasts and syncytiotrophoblasts of 7 weeks' gestation.

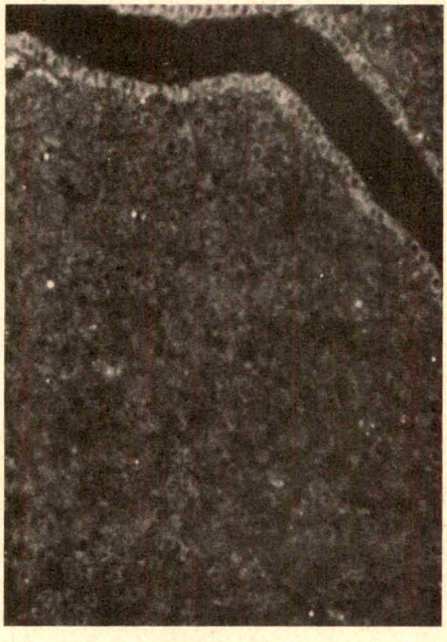

Fig. 8. Decidual tissue of 7 weeks' gestation after an application of normal rabbit serum. No immunoreactive cells are seen.

Fig. 10. Villous tissue treated with normal rabbit serum, immunofluorescent hCG-immunoreactive cells not seen.

addition, it has been shown that immunoreactive GIF is widely distributed in the pancreas and stomach as well as in the central nervous system.[6–9] On the other hand, immunoreactive GIF had never been demonstrated in the cells of chorionic villi and decidua. It is well known that chorionic villi produce some peptide hormones and steroids. Recently, Riddick and Kusmik.[10] reported that the amount of prolactin released from the decidua far exceeded a decrease in the tissue content of prolactin during incubation.

The releasing mechanism of the various peptide hormones from the chorionic villi and decidua is of

interest. In the rat hypothalamus, it was observed that a quantity of immunoreactive GIF is present in dendrites or axons of the nerve cells. However, a fluorescent reaction with anti-GIF was recognized neither in nerve fibers nor in nerve endings throughout the pancreas.[2, 6] In the present study, it was found with the use of RIA that GIF-like substance exists in the villi and decidua. Furthermore, the localization of GIF-like substance in the cells was demonstrated on the basis of the immunohistochemical method. On the basis of these findings, it is possible that GIF-like substance is present in the decidua and placenta. Whether or not villous and decidual GIF-like substances participate in the control of chorionic peptide or steroid secretion during gestation remains unknown.

Further investigation is necessary to elucidate the site of GIF synthesis.

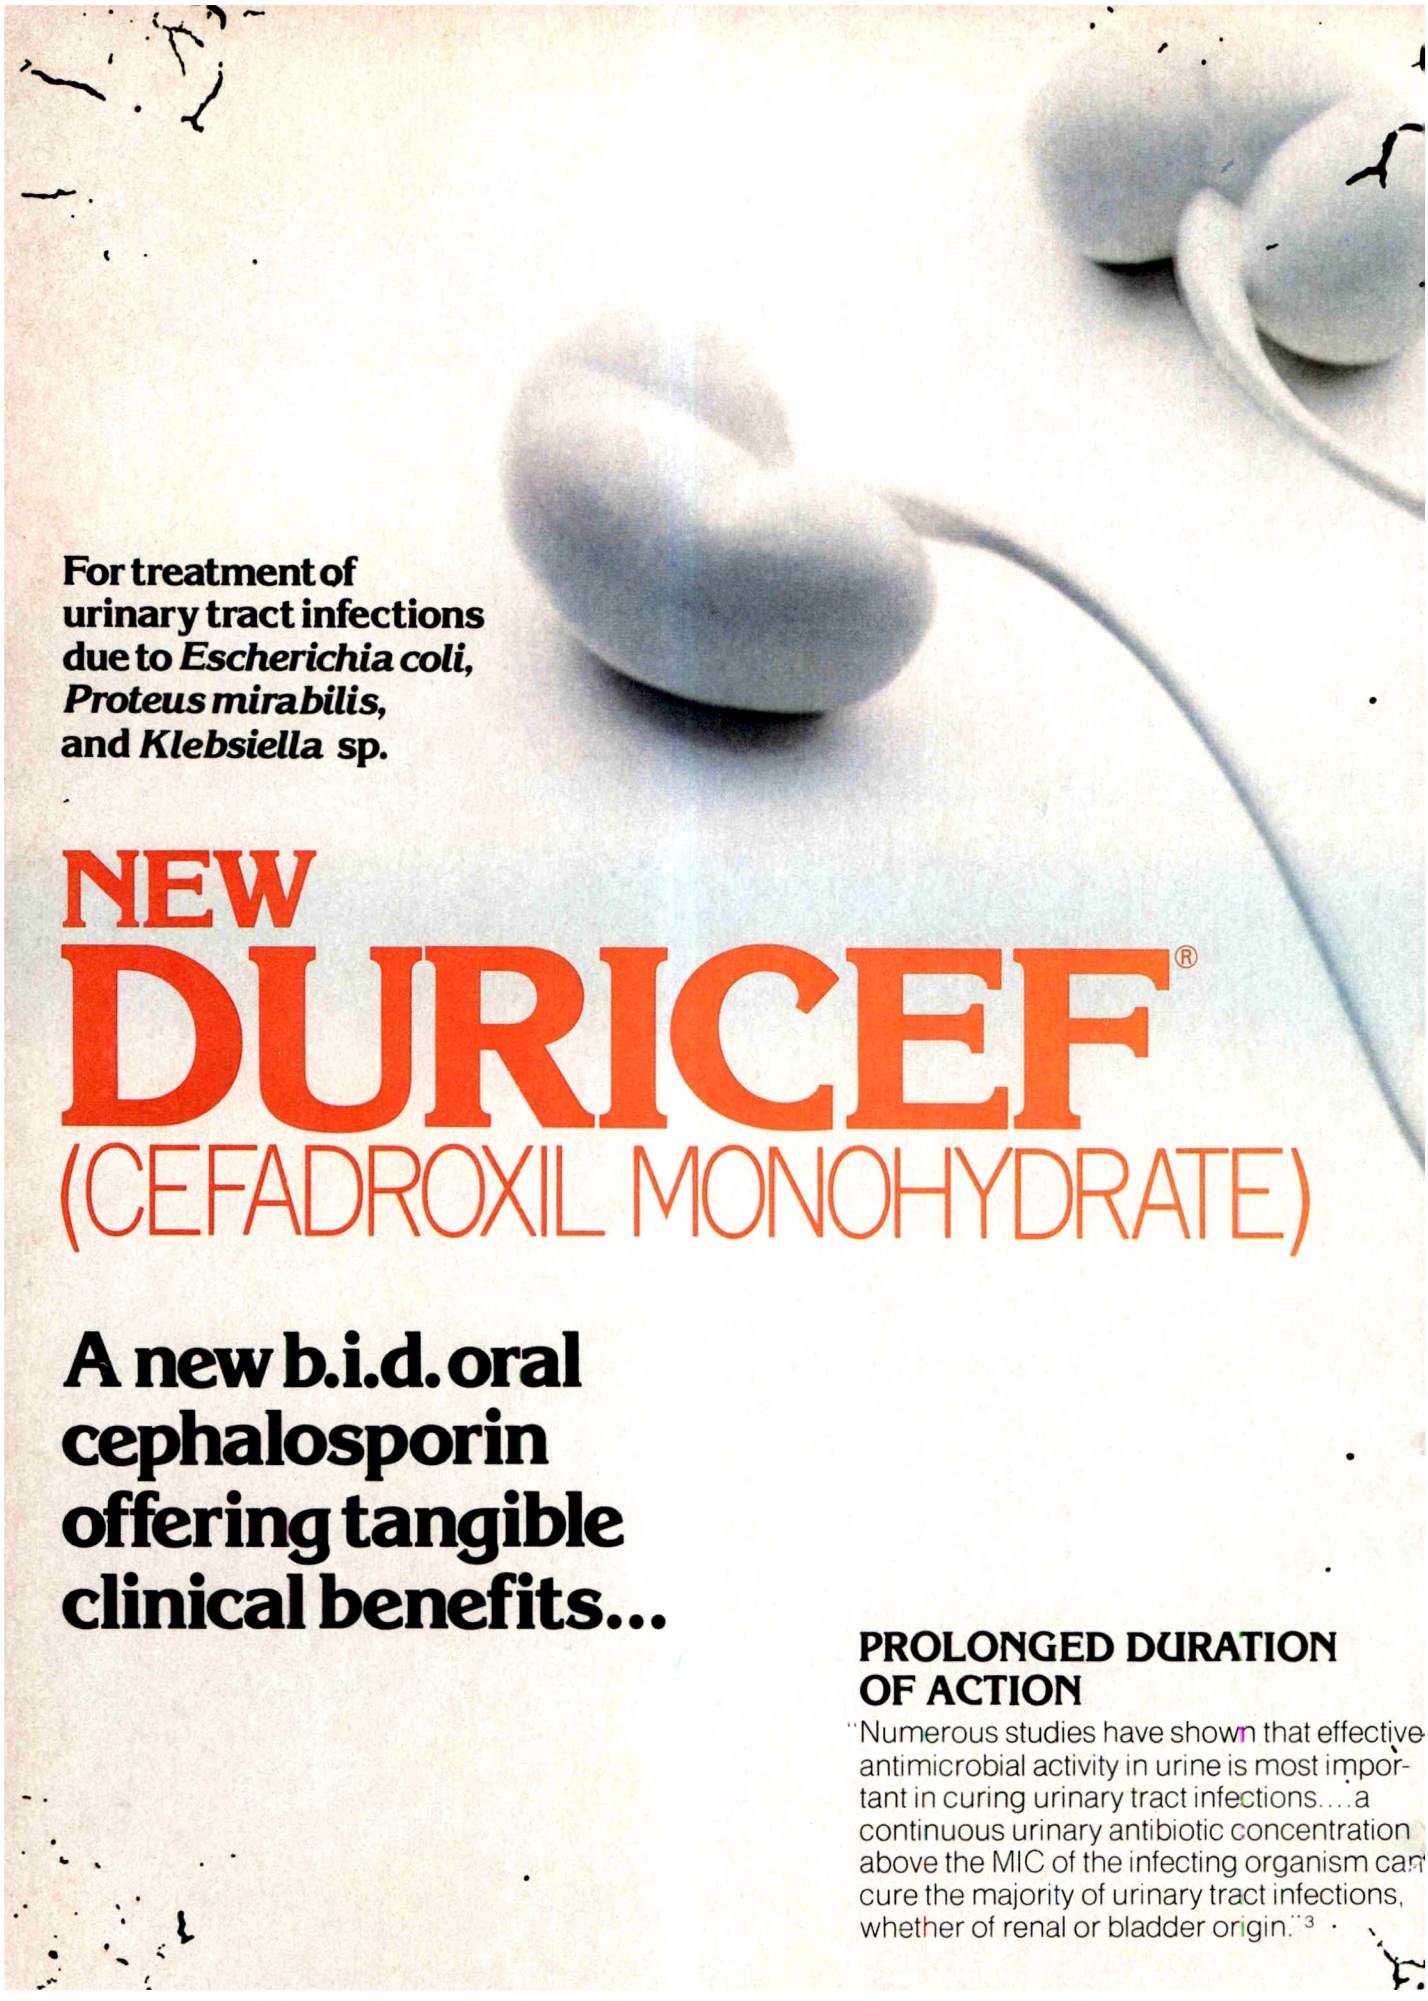
announces

NEW DURICEF®
(CEFADROXIL MONOHYDRATE)



A new oral cephalosporin for urinary tract infections due to *Escherichia coli, Proteus mirabilis,* and *Klebsiella* sp. distinguished by sustained, higher urine levels

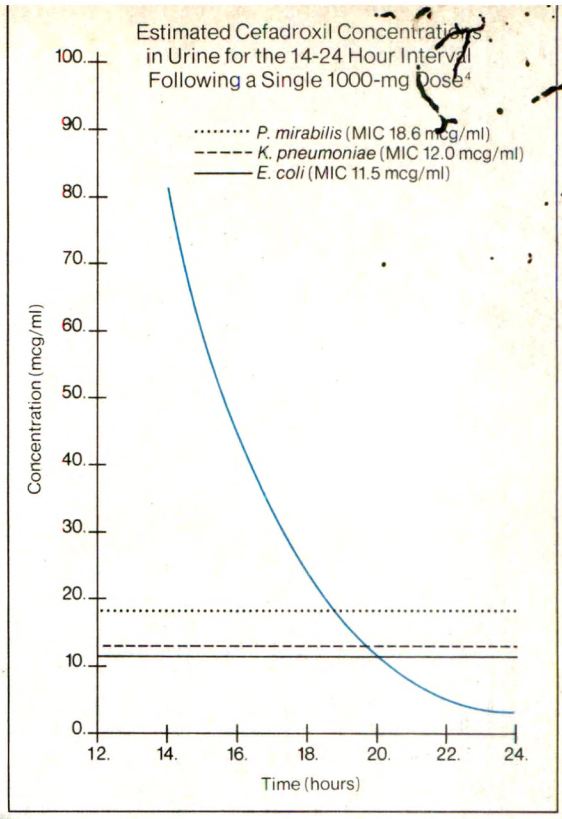
"Numerous human pharmacological studies have now clearly established that the outstanding metabolic characteristic of cefadroxil, which differentiates it from other presently marketed cephalosporins such as cephalexin and cephradine, is its prolonged duration of action."[1]

"...for cephalosporins, a longer half-life might be more useful than higher peak levels."[2]

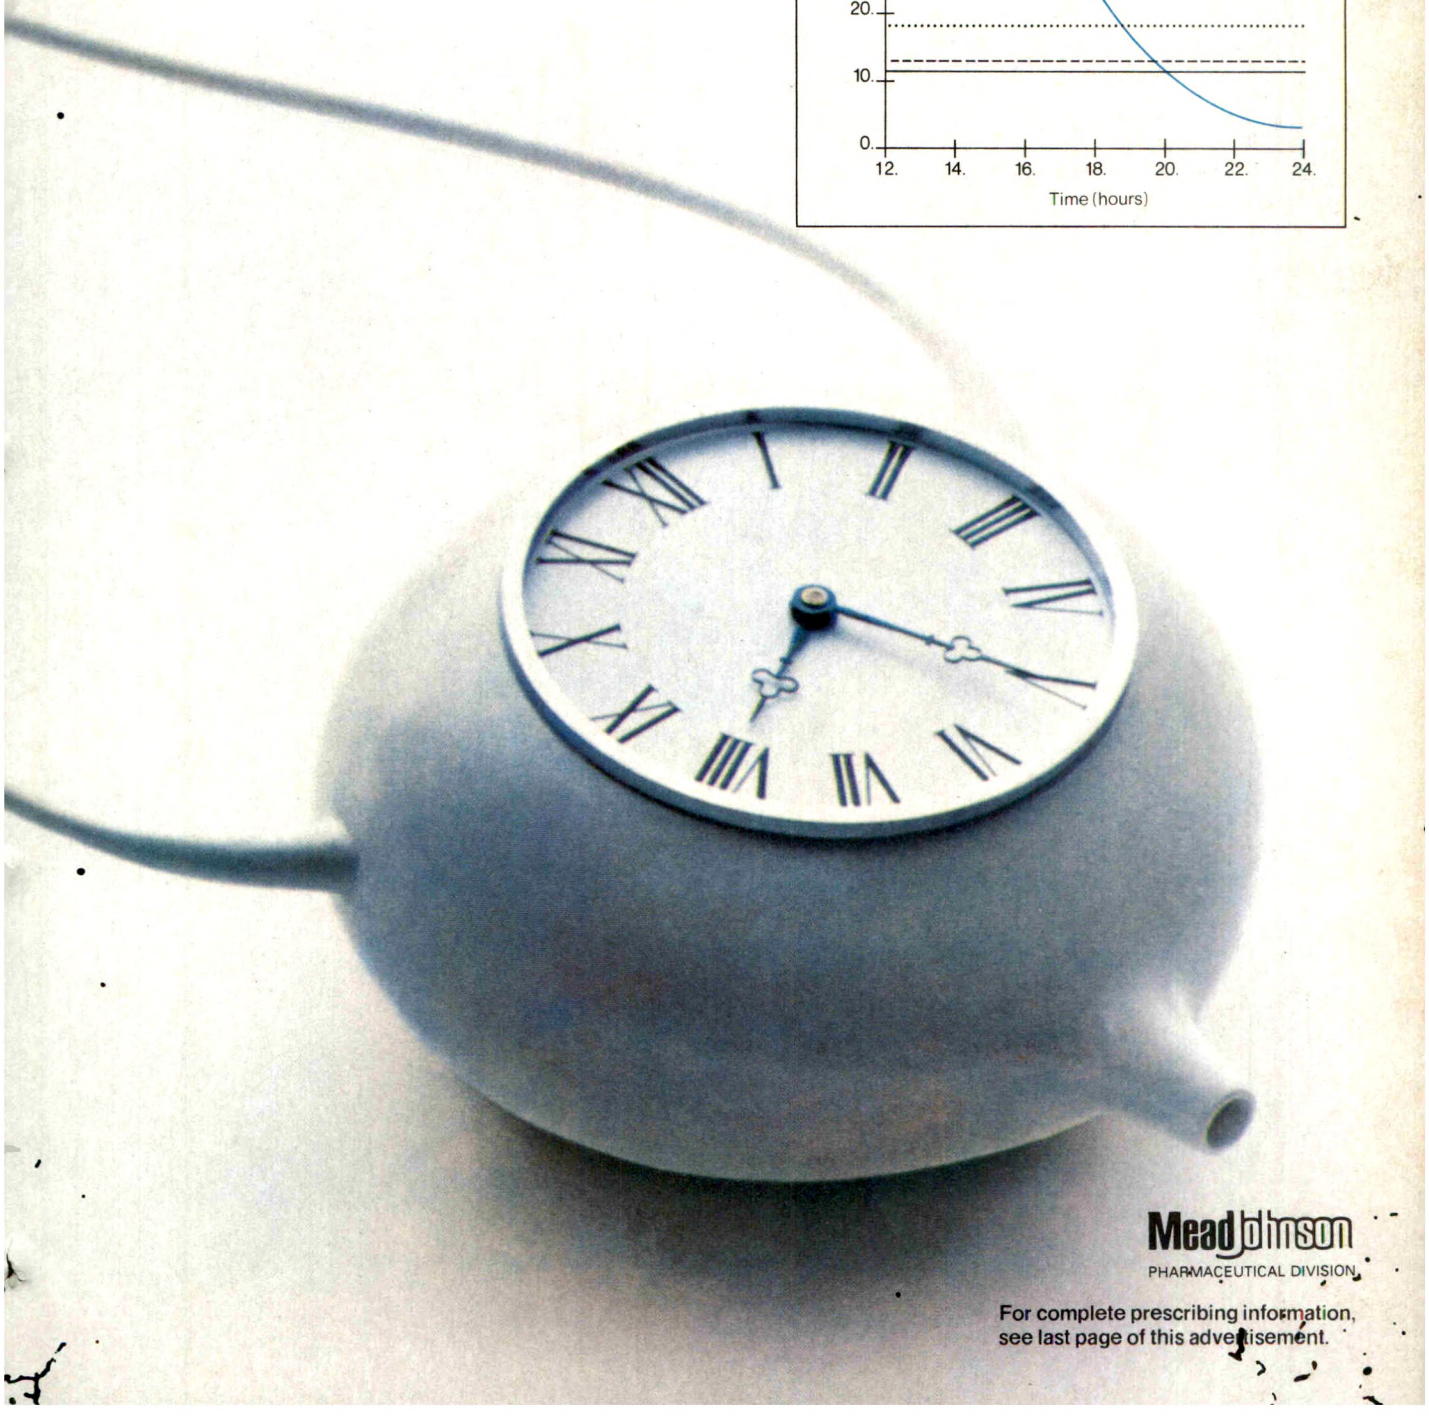
For complete prescribing information, see last page of this advertisement.

For treatment of urinary tract infections due to *Escherichia coli*, *Proteus mirabilis*, and *Klebsiella* sp.

NEW DURICEF®
(CEFADROXIL MONOHYDRATE)



A new b.i.d. oral cephalosporin offering tangible clinical benefits...



PROLONGED DURATION OF ACTION

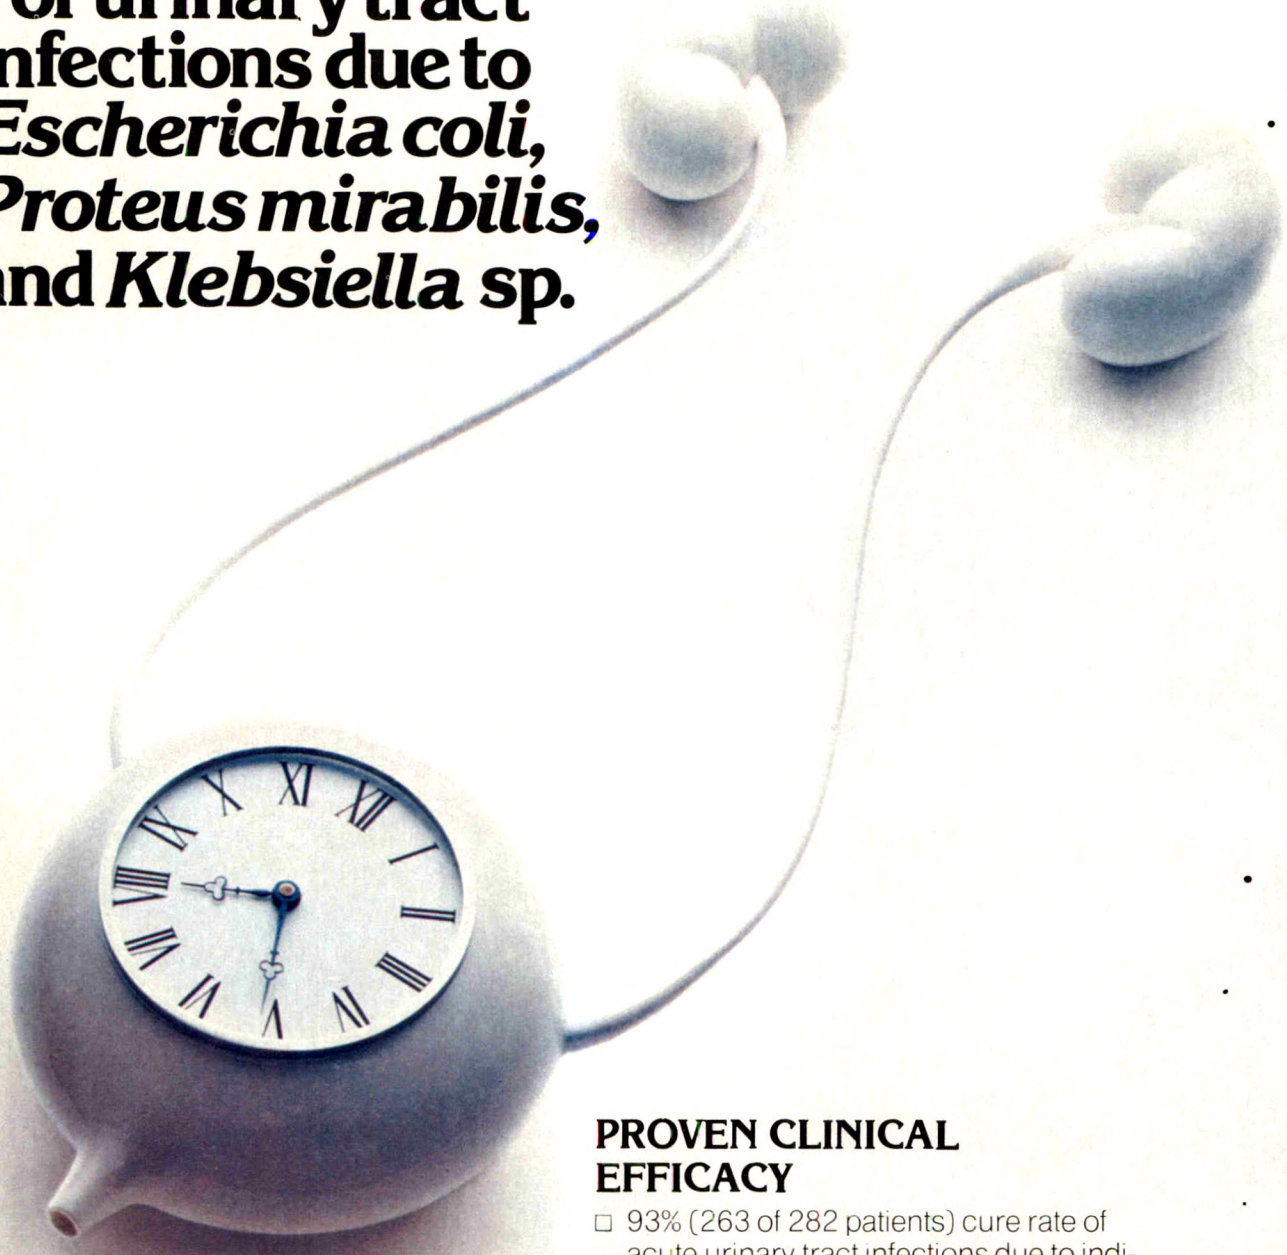
"Numerous studies have shown that effective antimicrobial activity in urine is most important in curing urinary tract infections....a continuous urinary antibiotic concentration above the MIC of the infecting organism can cure the majority of urinary tract infections, whether of renal or bladder origin."[3]

SUSTAINED HIGHER URINE LEVELS

- Cefadroxil concentration in urine is maintained well above the MICs for all typical urinary pathogens for 12 hours and, in most instances, for 18 hours.[3]
- After single equivalent doses, the antibiotic concentration in urine is three times higher for cefadroxil at 6 to 12 hours than for cephalexin.[3]
- The prolonged duration of action is due to a more gradual urinary excretion rate compared to cephalexin and cephradine.[1,3]
- Twenty-four hours after ingestion, approximately 93% of cefadroxil is recovered in the urine.[3]

Mead Johnson
PHARMACEUTICAL DIVISION

For complete prescribing information, see last page of this advertisement.



NEW

CAPSULES, 500 mg.

DURICEF®

(CEFADROXIL MONOHYDRATE)

For urinary tract infections due to *Escherichia coli*, *Proteus mirabilis*, and *Klebsiella* sp.

PROVEN CLINICAL EFFICACY

- 93% (263 of 282 patients) cure rate of acute urinary tract infections due to indicated organisms in the patients treated with cefadroxil (two 500-mg. capsules b.i.d.) in numerous multicenter studies.[5]

HIGH DEGREE OF SAFETY

- Laboratory parameters in more than 175 studies in 15 countries have failed to reveal any drug-related changes regarded as clinically significant.[4]
- In none of these studies was there any tendency for cefadroxil to accumulate in the serum nor has nephrotoxicity been reported.[4]
- DURICEF can be used in patients with renal insufficiency at reduced dosages (see full prescribing information).
- There is evidence of partial cross-allergenicity between the penicillins and the cephalosporins.
- The most frequent adverse reaction has been nausea...rarely severe enough to warrant cessation of therapy. Administration with food decreases the chances of nausea occurring and does not affect absorption.

B.I.D. CONVENIENCE AND COMPATIBILITY WITH FOOD

B.I.D. CONVENIENCE

Sustained high urine levels in comparison with other oral cephalosporins justify a simple two-capsule b.i.d. regimen in urinary tract infections.

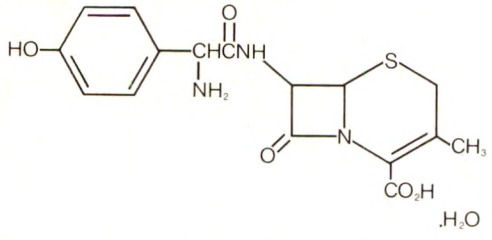
COMPATIBILITY WITH FOOD

Concomitant administration of DURICEF with food does not affect its rate or extent of absorption. This may be helpful in diminishing potential gastrointestinal complaints occasionally associated with oral cephalosporin therapy.

ENHANCED DOSAGE COMPLIANCE

The convenient regimen of DURICEF—two capsules b.i.d., at breakfast and dinner—improves the chances for patient compliance and increases the likelihood of patients completing therapy as prescribed.

Mead Johnson
PHARMACEUTICAL DIVISION



For complete prescribing information, see following page.

DURICEF®
(CEFADROXIL MONOHYDRATE)

A new oral cephalosporin offering tangible clinical benefits... plus b.i.d. convenience

DESCRIPTION: DURICEF® (cefadroxil monohydrate) is a semisynthetic cephalosporin antibiotic intended for oral administration. It is a white to yellowish-white crystalline powder. It is soluble in water and it is acid-stable. It is chemically designated as 7-[[D-2-amino-2-(4-hydroxyphenyl)acetyl]amino]-3-methyl-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid monohydrate. It has the following structural formula:

Clinical Pharmacology—DURICEF (cefadroxil monohydrate) is rapidly absorbed after oral administration. Following single doses of 500 and 1000 mg., average peak serum concentrations were approximately 16 and 28 mcg./ml., respectively. Measurable levels were present 12 hours after administration. Over 90 percent of the drug is excreted unchanged in the urine within eight hours. Peak urine concentrations are approximately 1800 mcg./ml. during the period following a single 500 mg. oral dose. Increases in dosage generally produce a proportionate increase in DURICEF urinary concentration. The urine antibiotic concentration was maintained well above the MIC of all typical urinary pathogens for 12 hours and, in most instances, for 18 hours.

MICROBIOLOGY: *In vitro* tests demonstrate that the cephalosporins are bactericidal because of their inhibition of cell-wall synthesis. DURICEF is active against the following organisms *in vitro*:

Escherichia coli — *Klebsiella species*
Proteus mirabilis

Note—Most strains of *Enterococci (Streptococcus faecalis* and *S. faecium)* are resistant to DURICEF. It is not active against most strains of *Enterobacter species, P. morganii,* and *P. vulgaris.* It has no activity against *Pseudomonas* or *Herella species.*

Disc Susceptibility Tests—Quantitative methods that require measurement of zone diameters give the most precise estimates of antibiotic susceptibility. One recommended procedure (CFR Section 460.1) uses cephalosporin class disc for testing susceptibility; interpretations correlate zone diameters of this disc test with MIC values for DURICEF. With this procedure, a report from the laboratory of "resistant" indicates that the infecting organism is not likely to respond to therapy. A report of "intermediate susceptibility" suggests that the organism would be susceptible if the infection is confined to the urinary tract, as DURICEF produces high antibiotic levels in the urine.

INDICATIONS: DURICEF (cefadroxil monohydrate) is indicated for the treatment of urinary tract infections caused by *E. coli, P. mirabilis,* and *Klebsiella species.*

Note—Culture and susceptibility tests should be initiated prior to and during therapy. Renal function studies should be performed when indicated.

CONTRAINDICATION: DURICEF (cefadroxil monohydrate) is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNING: IN PENICILLIN-ALLERGIC PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE USED WITH GREAT CAUTION. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PENICILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES OF PATIENTS WHO HAVE HAD REACTIONS TO BOTH DRUGS (INCLUDING FATAL ANAPHYLAXIS AFTER PARENTERAL USE).

Any patient who has demonstrated a history of some form of allergy, particularly to drugs, should receive antibiotics cautiously and then only when absolutely necessary. No exception should be made with regard to DURICEF (cefadroxil monohydrate).

PRECAUTIONS: Patients should be followed carefully so that any side-effects or unusual manifestations of drug idiosyncrasy may be detected. If a hypersensitivity reaction occurs, the drug should be discontinued and the patient treated with the usual agents (e.g., epinephrine or other pressor amines, antihistamines, or corticosteroids).

DURICEF (cefadroxil monohydrate) should be used with caution in the presence of markedly impaired renal function (creatinine clearance rate of less than 50 ml/min/1.73 M^2). (See Dosage and Administration.) In patients with known or suspected renal impairment, careful clinical observation and appropriate laboratory studies should be made prior to and during therapy.

Prolonged use of DURICEF may result in the overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Positive direct Coombs tests have been reported during treatment with the cephalosporin antibiotics. In hematologic studies or in transfusion cross-matching procedures when antiglobulin tests are performed on the minor side or in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it should be recognized that a positive Coombs test may be due to the drug.

USAGE IN PREGNANCY: Although no teratogenic or anti-fertility effects were seen in reproductive studies in mice and rats receiving dosages greater than the normal human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

ADVERSE REACTIONS: Gastrointestinal—The most frequent side-effect has been nausea. It was infrequently severe enough to warrant cessation of therapy. Administration with food decreases nausea and does not decrease absorption. Diarrhea and dysuria have also occurred.

Hypersensitivity—Allergies (in the form of rash, urticaria, and angioedema) have been observed. These reactions usually subsided upon discontinuation of the drug.

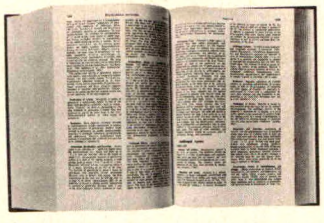
Other reactions have included genital pruritus, genital moniliasis, vaginitis, and moderate transient neutropenia.

DOSAGE AND ADMINISTRATION: DURICEF (cefadroxil monohydrate) is acid stable and may be administered orally without regard to meals. Administration with food may be helpful in diminishing potential gastrointestinal complaints occasionally associated with oral cephalosporin therapy.

Adults—The usual adult dose is one g. (two 500 mg. capsules) two times per day for patients with normal renal function. In patients with renal impairment, the dosage of cefadroxil should be adjusted according to creatinine clearance rates to prevent drug accumulation. The following schedule is suggested. In adults, the initial dose is 1000 mg. of DURICEF (cefadroxil monohydrate) and the maintenance dose (based on the creatinine clearance rate [ml/min/1.73M^2]) is 500 mg. at the time intervals listed below.

Creatinine Clearances	Dosage Interval
0-10 ml/min	36 hours
10-25 ml/min	24 hours
25-50 ml/min	12 hours

Patients with creatinine clearance rates over 50 ml/min may be treated as if they were patients having normal renal function.



Children—Dosage and safety have not yet been established in children.

HOW SUPPLIED: DURICEF® (cefadroxil monohydrate) capsules 500 mg. for oral administration in an opaque maroon cap and opaque white body No. 0 hard gelatin capsule. On each half capsule printed in black is "MJ" and "500." Available in bottles of 24 capsules (NDC 0087-0784-41) and 100 capsules (NDC 0087-0784-42). U.S. Patent Re—29,164

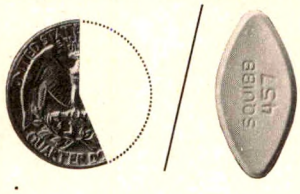
Good reasons to look at MYCOSTATIN® Vaginal Tablets (Nystatin Vaginal Tablets U.S.P.) again

Little or no resistance



"Repeated subculture of *Candida albicans* in increasing concentrations of nystatin results in little or no development of resistance..."[1] No occurrence of *in vivo* resistance as a general rule.

Virtually nontoxic and nonsensitizing

The manual application option

The fact that a vaginal tablet can be inserted *without* an applicator offers an important option when such a method is deemed advisable by the physician.

Economy

Your patients can save substantially compared to the cost of Miconazole Nitrate Cream or Clotrimazole Vaginal Tablets.*

Mycostatin® Vaginal Tablets

Nystatin Vaginal Tablets U.S.P.

[1]Goodman & Gilman, *The Pharmacological Basis of Therapeutics*, 5th Ed, 1975, p. 1236

*Based on manufacturers' published prices to retailers.

See following page for brief summary.

MYCOSTATIN® Vaginal Tablets
Nystatin Vaginal Tablets U.S.P.

MYCOSTATIN® VAGINAL TABLETS
Nystatin Vaginal Tablets USP

DESCRIPTION: Mycostatin Vaginal Tablets (Nystatin Vaginal Tablets USP) are provided as diamond-shaped compressed tablets containing 100,000 units of nystatin dispersed in lactose with ethyl cellulose, stearic acid, and starch.

INDICATIONS AND USAGE: This product is effective for the local treatment of vulvovaginal candidiasis. Confirm diagnosis by KOH smears and/or cultures prior to therapy. Rule out Trichomonas and *H. vaginalis* by appropriate laboratory methods since these pathogens do not respond to nystatin.

CONTRAINDICATIONS: Contraindicated in patients with a history of hypersensitivity to any of the components of the tablets.

PRECAUTIONS: General—Discontinue therapy if sensitization or irritation is reported during use.

Laboratory Tests—Repeat microbiological studies to confirm diagnosis and rule out other pathogens before instituting another course of antimycotic therapy if there is a lack of response to nystatin vaginal tablets.

Usage in Pregnancy—No adverse effects or complications have been attributed to nystatin in infants born to women treated with nystatin vaginal tablets.

ADVERSE REACTIONS: Nystatin is virtually nontoxic and nonsensitizing and is well tolerated by all age groups, even on prolonged administration. Rarely, irritation or sensitization may occur (see Precautions).

For full prescribing information, consult package insert.

HOW SUPPLIED: Available in packages of 15 and 30 individually foil wrapped tablets with applicator and in Unimatic®cartons of 50 single-dose packs per carton—each cello-protected single-dose pack consists of one individually foil wrapped tablet, one applicator, and one "Instructions for the Patient" leaflet.

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

GYNECOLOGY

Galactorrhea and pituitary tumors in postpill and non-postpill secondary amenorrhea

CHARLES M. MARCH, M.D.
DANIEL R. MISHELL, JR., M.D.
OSCAR A. KLETZKY, M.D.
ROBERT ISRAEL, M.D.
VAL DAVAJAN, M.D.
ROBERT M. NAKAMURA, PH.D.
Los Angeles, California

One hundred sixty-seven women with secondary amenorrhea were observed from six months to four years. In 66 patients, the amenorrhea followed the discontinuation of oral contraceptives (postpill) while in the remaining 101 the amenorrhea was not temporally pill related (non-postpill). Galactorrhea was present in 43 (65%) of those with postpill amenorrhea and in 32 (32%) of those with non-postpill amenorrhea ($p < 0.001$). Tomography of the sella turcica was performed in the 75 women with galactorrhea and in the 35 without galactorrhea who did not have withdrawal uterine bleeding following progesterone administration and who had low or normal serum follicle-stimulating hormone levels (hypothalamic-pituitary failure). Forty of the 75 patients with amenorrhea and galactorrhea had radiographic evidence of a pituitary tumor whereas only eight of 35 patients with hypothalamic-pituitary failure without galactorrhea had an abnormal sella turcica ($p < 0.01$). The incidence of radiographic abnormalities in those with galactorrhea was similar in both the postpill and non-postpill groups. (AM. J. OBSTET. GYNECOL. 134:45, 1979.)

THE MOST POPULAR contraceptive method in the United States is the use of oral contraceptive steroids.[1] These steroids are used by approximately 12 million women.[2] The incidence of amenorrhea of more than six months after discontinuation of oral contraceptives is estimated to be between 0.2 and 0.8%.[3, 4]

Recently, pituitary tumors have been reported to occur in patients with postpill amenorrhea with or without galactorrhea.[5] It is not known whether these tumors are induced by oral contraceptives or whether the steroid-associated withdrawal bleeding and inhibition of lactation mask the major symptoms of pituitary tumors.

This study was undertaken to ascertain if women who develop postpill amenorrhea differ from women with secondary amenorrhea *not* following oral contraceptive use.

Median	24	35
Amenorrhea without galactorrhea	23 (35%)	69 (68%)
Amenorrhea and galactorrhea	43 (65%)	32 (32%)

Materials and methods

The records of all Endocrine-Infertility Clinic patients presenting with secondary amenorrhea between July, 1974, and June, 1977, were reviewed. Criteria for inclusion in the study group were: (1) secondary amenorrhea of at least six months' duration, (2) no prior therapy with injectable steroidal contraceptives, (3) age less than 40 years, (4) no pregnancy within the previous 12 months, and (5) no breast-feeding for at least two years. Patients with elevated serum levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) were diagnosed as having ovarian failure and none of these patients was included.[6] A total of 167 patients between 16 and 39 years of age met these criteria (Table I).

Sixty-six patients had no spontaneous menses following the discontinuation of oral contraceptives. These patients were placed in the postpill category. In the other 101 patients there was no such temporal relation between the amenorrhea and oral contraceptive use. These patients were placed in the non-postpill category. At the initial visit, following a history and complete physical examination, the patients were further classified by the presence or absence of galactorrhea into four groups: (1) postpill amenorrhea (PPA), 23 patients; (2) postpill amenorrhea and galactorrhea (PPAG), 43 patients; (3) non-postpill amenorrhea (NPPA), 69 patients; and (4) non-postpill amenorrhea and galactorrhea (NPPAG), 32 patients. The women with galactorrhea had bilateral breast secretions which were either spontaneous or elicited by gentle pressure. The estrogen status of all patients without galactorrhea was determined by intramuscular administration of progesterone in oil.[6] Serum levels of FSH and LH were measured in all patients. Serum prolactin (PRL) levels were measured only in the 75 patients with galactorrhea. All assays were performed by previously described radioimmunoassay techniques.[7, 8] In this laboratory, the 95% confidence limits of hormone values during the follicular phase of normal ovulatory cycles are 3.2 to 9.0 mI.U./ml for FSH, 5 to 25 mI.U./ml for LH, and 9 to 20 ng./ml for PRL.

Hypocycloidal tomograms of the sella turcica were obtained in 110 patients—the 75 patients with galactorrhea as well as the 35 patients without galactorrhea who did not have withdrawal bleeding following progesterone administration and who had low or normal serum FSH levels (hypothalamic-pituitary failure).[6] The latter two categories were selected for sellar tomography since in a prior study abnormal pituitary fossa roentgenograms were reported to occur only in patients with these characteristics.[6] Polytomograms were interpreted by one neuroradiologist without knowledge of the patient's history or laboratory data. The tomograms were considered abnormal if there was inferolateral asymmetry of sella floor exceeding 2 mm. with associated erosion of the lamina dura.[9] Roentgenography was performed annually in all patients whose symptoms persisted.

Results

Postpill patients. Of the 66 patients in this category, 30 (45%) had oligomenorrhea prior to oral contraceptive use and 18 (27%) were parous (Table I). The length of amenorrhea varied between six and 132 months with a median of 24 months. The duration of oral contraceptive use ranged from one to 132 months with a median of 29 months. The mean age at the time oral contraceptive use was begun was 21 years with a range of 14 to 32 years.

Of these patients, 23 (35%) did not have galactorrhea and were characterized as having PPA (Table I). The other 43 (65%) had galactorrhea and were characterized as having PPAG. Of the 30 patients with prior oligomenorrhea, 19 developed PPA and 11 had PPAG.

PPA. Of the 23 patients with PPA, 13 had uterine bleeding following progesterone administration and 10 did not bleed. Of the 13 patients who had withdrawal bleeding, three had elevated LH but normal FSH levels in serum and the remaining 10 patients had normal FSH and LH concentrations. The 10 patients who did not have withdrawal bleeding had either low or normal serum LH and FSH values. Only two of the patients who failed to have withdrawal bleeding after progesterone had abnormal tomograms of the sella turcica. Initial and follow-up roentgenograms have remained normal in the other eight patients.

PPAG. Of these 43 patients, 17 had progesterone-induced withdrawal bleeding and 26 did not bleed. Serum LH and FSH levels were normal or low in the 43 patients with PPAG. Serum PRL levels were elevated (27 to 1,900 ng./ml) in 33 patients (77%).

Twenty-two patients (51%) had radiographic evidence of a pituitary tumor. Of these 22 patients, seven had withdrawal bleeding and 15 did not. Of the 33 patients with hyperprolactinemia, 20 had radiographic abnormalities.

Non-postpill patients. Of the 101 patients in this category, 37 (37%) had oligomenorrhea prior to the onset of amenorrhea and 32 (32%) were parous (Table I). At the time of referral to the clinic, these patients had been amenorrheic between six months and 18 years with a median of 35 months.

Of the 101 patients, 69 (68%) did not have galactorrhea and were classified as having NPPA (Table I). The other 32 (32%) had galactorrhea and were classified as having NPPAG. Of the 37 patients with prior oligomenorrhea, 26 had NPPA and 11 developed NPPAG.

NPPA. Of the 69 patients with NPPA, 44 had withdrawal bleeding following progesterone and 25 did not. All of these patients had normal or low serum LH and FSH levels. Tomograms of the sella turcica revealed abnormalities in six of the 25 patients who failed to respond to progesterone.

NPPAG. Of the 32 patients with NPPAG, 11 had withdrawal bleeding following intramuscular progesterone and 21 did not. All patients had normal serum levels of FSH and LH. Serum PRL levels were elevated (27.5 to 2,900 ng./ml) in 21 of these patients (66%).

Of these patients, 18 (56%) had radiographic evidence of a pituitary tumor while 14 (44%) had normal roentgenograms. Only two of the 18 patients with abnormal roentgenograms had bleeding after progesterone administration. Of the 21 patients who had elevated PRL levels, 15 had abnormal tomograms.

Radiographic abnormalities. Because the prevalence of abnormal roentgenograms in the PPAG group (51%) was similar to that in those with NPPAG group (56%), the two groups were combined and compared to those postpill and non-postpill patients without galactorrhea who had hypothalamic-pituitary failure. Of the 75 patients with amenorrhea and galactorrhea (PPAG and NPPAG), 40 (53%) had radiographic evidence of a pituitary tumor whereas only eight of the 35 patients (23%) without galactorrhea had radiographic evidence of a pituitary tumor. This difference is statistically significant ($p < 0.01$).

Comment

In this study, 45% of the patients in the postpill category had a prior history of oligomenorrhea. However, this percentage is not significantly different from the finding of previous oligomenorrhea in 36% of the patients from the non-postpill group. This suggests that a significant number of women who have oligomenorrhea may become amenorrheic at a later date irrespective of oral contraceptive use. Although it has been suggested that a causal relation exists between oligomenorrhea and the development of secondary amenorrhea following oral contraceptive treatment, the natural history of oligomenorrhea with and without contraceptive steroid use is unknown.[11] Also, the incidence of galactorrhea in both the postpill and non-postpill groups was not higher among patients who had prior oligomenorrhea. These data suggest that there may be no relation between present menstrual pattern and the subsequent occurrence of galactorrhea in those who develop amenorrhea.

The incidence of galactorrhea was significantly higher in women with postpill amenorrhea than in patients from the non-postpill group ($p < 0.001$). These data indicate a relation between oral contraceptive use and the development of galactorrhea in women who became amenorrheic after discontinuing the use of oral steroid contraceptives.

Amenorrheic women who have hypothalamic-pituitary failure and those with galactorrhea irrespective of whether or not they have progesterone withdrawal bleeding should have roentgenography of the sella turcica. This is supported by the finding of abnormal tomograms in 23% and 53%, respectively, of these two groups of patients. Amenorrheic women with galactorrhea compared with the group having hypothalamic-pituitary failure and no galactorrhea had a significantly greater incidence of abnormal sella turcica roentgenograms. Pituitary tumors were found in a high percentage of women with galactorrhea independent of estrogen status. Thus, unlike women who have only amenorrhea, all of those with galactorrhea, regardless of estrogen status, should have roentgenography of the sella turcica. This increased incidence of radiographic abnormalities was similar in both the PPAG and NPPAG groups. However, it should be noted that 65% of the women who developed amenorrhea following oral contraceptive use had galactorrhea compared with only 32% of the patients in the non-postpill category. Therefore, the difference in the proportion of radiographic abnormalities compatible with a pituitary tumor is related to the significantly greater incidence of galactorrhea; since galactorrhea is more frequent in patients with postpill amenorrhea, these patients are in a higher risk category for presence of a pituitary tumor.

The cause of the high incidence of galactorrhea and pituitary tumors observed in women with amenorrhea following termination of oral contraceptives cannot be explained at present. Because both estrogens[8, 12, 13] and

gestagens[14, 15] have been shown to stimulate PRL release, oral contraceptive steroid preparations may be causally related to the development of galactorrhea, by direct stimulation of the pituitary lactotrophs, by inhibition of the release of prolactin-inhibiting factor, or by stimulation of the growth of very small asymptomatic pituitary tumors.[16] In order to determine whether a causal relationship exists between the use of oral contraceptives and the development of pituitary tumors, it will be necessary to perform a retrospective case-control study.

The reagents used for LH, FSH, and PRL assays were supplied by the National Institute of Arthritis, Metabolism, and Digestive Diseases, Bethesda, Maryland.

Surgical treatment of prolactin-secreting microadenomas

R. HERBERT WIEBE, M.D.
RICHARD S. KRAMER, M.D.
CHARLES B. HAMMOND, M.D.
Durham, North Carolina

Fourteen women (aged 19 to 38 years) with amenorrhea of 1 to 7 years' duration underwent transsphenoidal pituitary exploration for selective removal of potential prolactin secreting microadenomas. Preoperatively, serum prolactin levels were elevated in all (90 to 970 ng/ml), standard sella turcica x-ray films were normal, but polytomography revealed localized erosion in 12 women. Growth hormone reserve (assessed with insulin-induced hypoglycemia) was compromised in one of 13 women; cortisol responsiveness (to insulin-induced hypoglycemia) was attenuated in three of 10 women, while gonadotropin reserve (assessed with subcutaneous 100μg luteinizing hormone–releasing factor) was borderline in two of 13 women. At operation, pituitary adenomas were removed in 13 women, while a sellar diverticulum was found in the remaining woman. In the 13 women with pituitary adenoma removal, plasma prolactin levels decreased in all and reached normal levels in five women. Despite pituitary surgery, trophic hormone function (i.e., growth hormone reserve, cortisol responsiveness, thyroid-stimulating hormone, follicle-stimulating hormone, and luteinizing hormone) was preserved in most instances and perhaps improved. Adjunctive radiotherapy was utilized in two patients. With follow-up of 6 months' to 3 years' duration, cyclic menses have resumed in six and pregnancy occurred in three of seven women desiring fertility. Factors associated with successful surgical treatment of these microadenomas included: (1) tumor size (<8 mm in diameter), (2) surgical technique, and (3) the surgeon's operative experience.
(AM. J. OBSTET. GYNECOL. 134:49, 1979.)

WIDE AVAILABILITY of sophisticated radiologic techniques[1] and increasingly sensitive laboratory assays of hypothalamic pituitary hormones[2] have allowed a more frequent identification of a small prolactin-secreting adenoma (microadenoma) of the pituitary in some hyperprolactinemic-amenorrheic women. The treatment of these tumors remains controversial and various therapeutic modalities have been advocated, including surgical extirpation,[3] radiotherapy,[4] and medical therapy[5] (i. e., bromoergocryptine). The experience of the Reproductive Endocrinology Division at Duke University Medical Center with surgical therapy (transsphenoidal resection of prolactin-secreting pituitary microadenomas) over a period of 2 years (January, 1975, to June, 1977) is reported.

From the Division of Reproductive Endocrinology, Department of Obstetrics and Gynecology, and Division of Neurosurgery, Department of Surgery, Duke University Medical Center.

Presented at the Annual Meeting of American College of Obstetricians and Gynecologists, Anaheim, California, April 8-13, 1978.

Received for publication August 16, 1978.

Material and methods

Fourteen women (aged 19 to 38 years) with amenorrhea of 1 to 7 years' duration were thoroughly studied prior to operation. Galactorrhea was present in 10 of the women. The onset of amenorrhea (with or without galactorrhea) was spontaneous in six of the patients, coincident with the discontinuation of oral contraceptives in six patients, post partum in one patient, and as a primary occurrence in one patient. Complete physical examination and formal visual field determinations were normal in all of the patients except for one who was congenitally blind. The relevant clinical aspects and laboratory data are summarized in Table I.

Normal laboratory values			+	0-20	4.6-22.0	6.5-24	4.6-10.7	5-20

TSH was normal in all patients.

Standard sella turcica x-ray films were normal in all 14 patients, while routine tomography was abnormal in two of seven patients studied. Thin-section (1 to 2 mm) polytomography (12 patients) was abnormal in 11 patients and equivocal in one patient. Carotid arteriography and pneumoencephalography, performed preoperatively in all patients, were normal. Comprehensive studies of pituitary function were conducted 4 to 6 weeks prior to operation.

Gonadotropic hormone reserve. A dosage of 100 μg of luteinizing hormone–releasing factor (LRF) (AY-24031*) was given subcutaneously to 13 of the 14 patients, whereupon serum luteinizing hormone (LH) and follicle-stimulating hormone (FSH) were assayed at −30, 0, 15, 30, 60, 120, and 240 minutes.

Growth hormone reserve. This was assessed in 13 of the 14 patients. After an overnight fast and 90 minutes following the placement of an indwelling venous catheter, regular insulin was injected intravenously in a dose of 0.1 U/kg of body weight; serum assays for growth hormone and glucose were obtained at 15 minute intervals for 90 minutes.

Assessment of hypothalamic-pituitary-adrenal axis. Plasma cortisol concentrations were determined at 0 and 90 minutes following the administration of insulin in 10 of the 13 patients in whom growth hormone secretion was studied. In two of the patients, the axis was assessed with urinary 17-hydroxycorticosteroid determination following oral metyrapone (750 mg every 4 hours for 6 doses).

Indications for surgical intervention, each weighed independently, included: (1) "significant" hyperprolactinemia (>100 ng/ml), (2) unequivocal radiographic abnormality (13 patients), (3) desire for pregnancy (seven patients).

The transsphenoidal approach to the sella was employed in all patients, and a pathologically confirmed microadenoma was identified and resected in 13, while an inferior sella diverticulum containing a minute volume of "abnormal" tissue was found in the remaining patient (Case No. 14); the tissue was removed but neither tumor nor lactotroph hyperplasia could be verified histologically.

In the 13 patients with confirmed microademonas, the surgical technique varied somewhat as experience grew. Tumor removal was effected by (1) simple suction and curettage of the tumor bed (five patients); (2) suction removal followed by placement of an ethanol-soaked pledget into the tumor cavity for 1 minute (in one patient); (3) suction and curettage of the tumor bed, with biopsy of the edges of the surrounding normal-appearing pituitary tissue (two patients); (4) suction and curettage of the tumor bed, with biopsy of the edges, followed by placement of an ethanol-soaked pledget for 1 minute in the tumor cavity (five patients). Tumor size varied from 3 to 10 mm in diameter. In Case No. 2, pleomorphism, increased mitotic activity, and mildly atypical changes were seen. In the remaining 12 patients, the histologic picture was entirely benign.

Eleven of the 13 patients with microadenomas were readmitted 10 to 14 weeks postoperatively for endocrine testing. Baseline hormonal studies (i.e., serum thyroid-stimulating hormone (TSH), prolactin, growth hormone, and plasma cortisol (A.M. and P.M.) were obtained. Gonadotropic hormone reserve, growth hormone reserve, and the hypothalamic-pituitary-adrenal axis were reassessed in all 11 patients. In the remaining

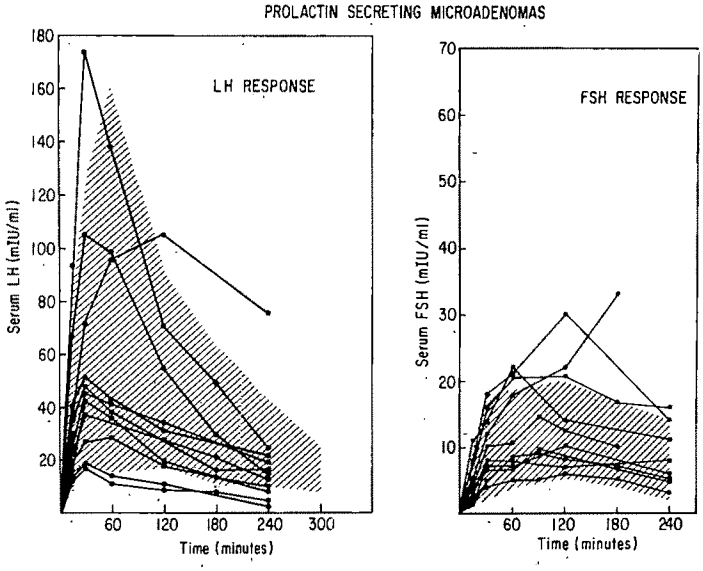

Fig. 1. Effect of LRF on serum LH and serum FSH levels in 11 women with prolactin-secreting microadenomas. The closed circles connected by lines represent the change from baseline of serum LH levels and serum FSH levels following the subcutaneous administration of 100 μg of LRF. The shaded area represents the range of response in 18 normal women studied in the early follicular phase.

two patients not admitted to the hospital, one was followed up with periodic determinations of prolactin, FSH, LH, thyroxine, and urinary 17-hydroxycorticosteroids, while the other was not tested as she conceived 4 to 5 weeks postoperatively.

Adjunctive radiotherapy (i.e., 5,000 rads) was recommended in Case Nos. 1, 2, and 3 (significant hyperprolactinemia postoperatively) and was initiated in Case Nos. 1 and 2 6 and 7 months postoperatively, respectively. In Case 3 adjunctive radiotherapy was refused. Follow-up on all patients extends from 5 months to 3 years. In Cases 3 and 6 the patients were lost to follow-up at 6 months.

Serum prolactin,[6] TSH,[7] LH,[7] FSH,[7] and growth hormone[8] were determined by radioimmunoassay. Serum thyroxine was assayed by competitive protein-binding radioassay.[9] Plasma cortisol levels were measured by competitive protein binding.[10] Laboratory values for women were: follicular phase FSH, 4.6 to 22 mIU/ml; follicular phase LH, 6.5 to 24.2 mIU/ml; prolactin, 0 to 20 ng/ml; TSH, 0 to 10 mU/ml; thyroxine, 4.6 to 10.7 μg/100 ml.

Results

The immediate postoperative course of the patients was uncomplicated with the exception of transient diabetes insipidus in four patients.

Preoperative studies. In 12 of the patients, growth hormone secretion in response to insulin-induced hypoglycemia was normal according to the criteria of Eddy and associates.[11] One patient (Case No. 4) had no response.

A normal plasma cortisol response to insulin-induced hypoglycemia (greater than twofold rise from baseline) was noted in seven of 10 women tested. In Case No. 1 the patient had no response, while the cortisol response was attenuated (less than twofold rise from baseline) in Cases No. 7 and No. 8. Adrenocorticotropic hormone (ACTH) reserve, tested in two patients (Cases 4 and 9) with metyrapone, was normal.

Eleven patients had a normal LH response to LRF (compared to early follicular phase response) while two patients had a response which was borderline low (Cases 1 and 6) (Fig. 1).

Postoperative studies. Although not shown, serum TSH, baseline growth hormone levels, thyroxine, serum LH, serum FSH, plasma cortisol levels, and/or urinary 17-hydroxycorticosteroid hormones were normal in all patients studied postoperatively. As shown in Table II, prolactin levels decreased postoperatively in all patients. Prolactin levels were above 50 ng/ml (range 112 to 427) in three patients, between 20 and 50 ng/ml in five patients, and below 20 ng/ml in the remaining five patients.

In all 11 patients studied, growth hormone response to insulin-induced hypoglycemia was normal and essentially unchanged from preoperative studies. Growth hormone reserve was not tested in the one patient in whom preoperative studies had failed to demonstrate a response to insulin-induced hypoglycemia.

Table II. Prolactin-secreting microadenoma: postoperative follow-up

Table III. Surgical technique and postoperative prolactin levels

Technique	No. of patients	Prolactin level		
		> 50 ng/ml	20-50 ng/ml	< 20 ng/ml
Suction, curettage	5	2	3	-
Suction, currettage, and biopsy	2	-	1	1
Suction, ethanol pledget	1	1	-	-
Suction, curettage, biopsy, ethanol pledget	5	-	1	4

A normal plasma cortisol response to insulin-induced hypoglycemia was noted in nine patients, in two of whom an attenuated response had been demonstrated before operation. In Case No. 1 (no response preoperatively) the patient failed to respond. An attenuated response was noted in Case No. 9 (preoperative normal metyrapone testing); however, the baseline plasma cortisol level was mildly elevated and may have accounted for the failure to significantly increase plasma cortisol levels during stress.

The LH response to LRF was similar to the preoperative response in the 10 patients studied both preoperatively and postoperatively. Furthermore, the LH response in the patients in whom cyclic menses resumed and in those who remained amenorrheic was similar (Fig. 2).

As shown in Table II, galactorrhea following pituitary surgery diminished in six and completely resolved in three patients. Cyclic menses resumed in five patients in 4 to 8 weeks following operation, all with prolactin levels less than 20 ng/ml. One patient (Case No. 10) became pregnant prior to reinstitution of menses and (by uterine size) probably conceived 4 to 5 weeks postoperatively; however, the pregnancy was terminated at 11 weeks for psychosocial reasons, with the subsequent development of cyclic menses. Of the five patients with cyclic menses, three desired pregnancy; one has conceived with a normal prenatal course and delivery, while the remaining two patients (8 and 17 months after operation) have not yet conceived. Of the remaining four patients desiring pregnancy, two have had postoperative radiotherapy, and one has been lost to follow-up, while ovulation induction with clomiphene citrate in the remaining patient resulted in conception and delivery of a viable infant at term.

Follow-up has extended from 6 months to 3 years. In the three patients with prolactin levels above 50 ng/ml, radiotherapy in two of the patients has resulted in a progressive decline in prolactin levels. In the remaining five patients in whom prolactin levels were modestly elevated immediately postoperatively, i.e., 8 to 12 weeks, prolactin levels have not changed in three (6 to 18 months' follow-up), while in one patient (Case No. 4) a stable level of prolactin was maintained for 12 months with the subsequent rapid increase resulting in

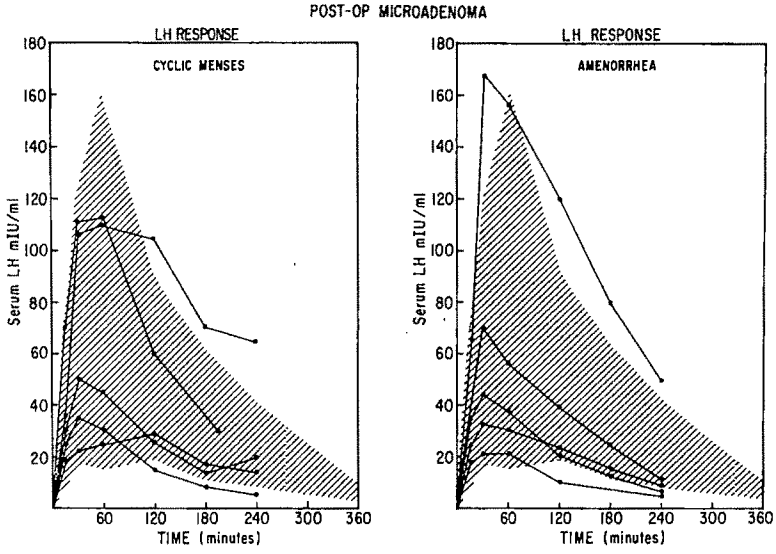

Fig. 2. Effects of LRF on serum LH levels in 10 women following resection of prolactin-secreting microadenomas. The responses (change from baseline of serum LH levels following the subcutaneous administration of 100 μg of LRF) of women with cyclic menses postoperatively are displayed on the right, while responses of those women remaining amenorrheic are displayed on the left. The shaded area represents the range of response in 18 normal women studied in the early follicular phase.

re-exploration of the sella and extirpation of a recurrent tumor with evidence of suprasellar extension. The remaining patient (Case No. 13) has only recently been delivered, and a follow-up prolactin level, obtained 4 months post partum, was normal (2.7 ng/ml).

Prolactin levels have remained normal in the five patients (8 to 36 months' follow-up) in whom initial postoperative prolactin levels were normal.

Differences in surgical technique were compared to the results obtained and are shown in Table III. In the five patients in whom tumor removal was effected by suction and curettage alone, all had elevated prolactin levels postoperatively, while four of the five patients in whom suction, curettage, biopsy of contiguous normal pituitary, and placement of an ethanol pledget into the tumor cavity were carried out were euprolactinemic postoperatively.

A comparison between preoperative prolactin levels, tumor size, and postoperative prolactin levels is shown in Table IV. Of the five patients with tumors larger than 8 mm in diameter, postoperative prolactin levels were greater than 50 ng/ml in three, between 20 and 50 ng/ml in one, and within the normal range in one patient. In contrast, four of the seven patients with tumors less than 8 mm in diameter had normal postoperative prolactin levels while three had levels between 20 and 50 ng/ml. In the four patients with preoperative prolactin levels above 300 ng/ml, postoperative prolactin levels were elevated. Postoperative prolactin levels were normal in five of the nine patients with preoperative prolactin levels below 300 ng/ml.

Table IV. Prolactin-secreting microadenoma: Prolactin levels, surgical technique, and tumor size

Comment

Although a major neurosurgical procedure, selective removal of pituitary microadenomas is a relatively innocuous procedure, as the negligible morbidity seen in this series suggests. Despite pituitary surgery, trophic hormone function (i.e., TSH, growth hormone, and ACTH) was preserved in most instances and perhaps improved. Improvement of an attenuated cortisol re-

sponse to insulin-induced hypoglycemia following removal of prolactin-secreting microadenomas has been previously described.[12] This alteration, while interesting, defies explanation although the preoperative attenuated response seen in two of our patients may have been spurious. Although a normal gonadotropic response to LRF should reflect the integrity of the hypothalamic-pituitary-gonadal axis and provide an estimate of pituitary gonadotropin reserve, this test does not necessarily indicate normal function of the axis. The similarity of responses observed preoperatively and postoperatively and the similarity of responses (in the postoperative group) between those patients in whom cyclic menses resumed and those who remained amenorrheic appears to negate the predictive value of the LRF test.

The persistence of hyperprolactinemia in eight of the 13 patients is frankly disconcerting. Compromise of pituitary stalk function, secondary to surgical manipulation, seems an unlikely explanation, as one would expect only temporary disruption with rapid resolution. More permanent stalk damage is equally untenable, as compromise of other trophic hormones would be expected in this instance. Residual tumor seems the most probable explanation, particularly in Case Nos. 1, 2, and 3, since prolactin elevations of such magnitude could hardly be ascribed to inherent hypothalamic dysfunction. Certainly, the progressive decline in prolactin levels following radiotherapy in two of these patients further supports this hypothesis.

The modest elevations of prolactin (i.e., 20 to 50 ng) seen postoperatively in five of our patients is consistent with residual tumor but may reflect inherent hypothalamic dysfunction. Conceivably, chronic impairment of prolactin–inhibiting factor secretion could lead to moderate hyperprolactinemia or even localized adenomatous hyperplasia. Despite "removal" of an apparently focal tumor, a small number of lactotrophs may remain behind and continue to secrete prolactin unabated. The apparent stabilization of prolactin levels over a period of 6 to 18 months would be compatible with this hypothesis. On the other hand, among these five patients, tumor removal was effected in four with suction and curettage alone. Since we presently view this as less than optimal therapy, the persistence of hyperprolactinemia in these patients is considered most probably due to residual tumor, i.e., incomplete resection of the tumor margins. Certainly, the postoperative course in Case No. 4 indicates the necessity for close follow-up of all patients with modest elevation of prolactin postoperatively.

Five of the patients in this series were provided what we now regard as optimal surgical therapy: suction removal, curettage of the tumor cavity, biopsy of the surrounding normal-appearing pituitary tissue, and application of absolute ethanol to the cavity for 1 minute. Four of these patients (80%) were euprolactinemic postoperatively. This experience should be compared to that in the eight patients in whom attempted resection was less rigorous; only one of these patients (12.5%) was euprolactinemic postoperatively.

In addition to surgical technique, tumor size may be a determinant of success. In patients with tumors larger than 8 mm in diameter, only one of the five (20%) was euprolactinemic postoperatively. In contrast, among patients with tumors less than 8 mm in diameter, four of seven (57%) were euprolactinemic postoperatively.

Yet another important factor in the surgical outcome is the surgeon's personal operative experience with these lesions. Examination of results among the first 15 consecutive patients operated upon by a single person (RSK) reveals a significant chronological trend (five of these are excluded from the present series as a consequence of incomplete or short duration of follow-up); among the first three patients, one (No. 1) demonstrated marked hyperprolactinemia postoperatively while two patients (No. 5 and No. 6) demonstrated moderate persistent hyperprolactinemia (20 to 50 ng per milliliter). Among the next three patients operated upon, two (No. 10 and No. 13) demonstrated modest postoperative elevations of prolactin (both of these patients have conceived), while the third (No. 11) became euprolactinemic. Operations performed on the next nine patients resulted in persistent and significant postoperative hyperprolactinemia in two, and normal prolactin levels in the remaining seven (78% "endocrinologic cure"). It would thus appear that increasing experience with these tumors is also a major determinant of success.

Our experience then suggests that the surgical therapy of pituitary microadenomas should include thorough curettage of the tumor bed and biopsy of surrounding normal-appearing pituitary tissue, followed by application of absolute ethanol to the tumor cavity. The preservation of trophic hormone function in our patients despite biopsy and alcohol treatment of pituitary tissue further supports an aggressive approach in the treatment of these tumors. Furthermore, our experience favors early treatment of these tumors, inasmuch as the "cure" rate appears inversely related to tumor size.

Finally, improved results can be anticipated as the surgeon's experience with these tumors increases.

The purpose of this study was to compare the steroidogenic potential of the granulosa, theca, and medullary tissues from polycystic and normal ovaries. These ovarian endocrine compartments were isolated from appropriate ovaries and were cultured in vitro for three days in the absence (control) and presence of follicle-stimulating hormone (FSH)/luteinizing hormone (LH) (1 IU/ml), N^6,O^2-dibutyryladenosine-3′:5″-cyclic monophosphoric acid (Bu_2cAMP) ($10^{-2}M$), and adrenocorticotropic hormone (ACTH) (1.3 U/ml). After the incubation, steroids in the media were measured by radioimmunoassay. Granulosa cells (10^5 cells per dish) from 4 to 7 mm follicles of normal and polycystic ovaries secreted progesterone spontaneously during the culture period and the production of progesterone spontaneously during the culture period and the production of progesterone was markedly stimulated (between tenfold and thirtyfold) by gonadotropins and Bu_2cAMP but not by ACTH. Little, if any, androgen (androstenedione, dehydroepiandrosterone, and testosterone) or estrogen (estrone and estradiol) accumulated in the media of any granulosa cell culture. The control cultures of theca tissue from normal and polycystic ovaries secreted large amounts of androstenedione and progesterone and the production of these steroids by normal and polycystic ovary theca was stimulated in most cases by LH/FSH and Bu_2cAMP but not by ACTH. Both normal and polycystic ovary theca secreted some testosterone and dehydroepiandrosterone but little, if any, estrone or estradiol accumulated in any theca culture. The medullary tissue of normal and polycystic ovaries produced only trace amounts of steroids in vitro except for the results from one polycystic ovary with hyperthecosis in which case significant quantities of C_{19} and C_{18} steroids were secreted. These experiments have demonstrated that isolated granulosa and theca cells from midantral follicles of normal and polycystic ovaries have a similar capacity to secrete C_{21} and C_{19} steroids in the absence and presence of trophic agents. Therefore, it seems probable that chronic anovulation in patients with polycystic ovaries is not caused by an obvious deficiency in the de novo steroidogenic potential of the multiple midantral follicles of the polycystic ovaries or by the absence of gonadotropin receptors on the polycystic ovary follicular cells. PREVIOUS studies of protein hormone concentrations in the sera of patients with polycystic ovarian disease (PCO) have been unable to define the primary cause of this pathophysiologic state. Elevated luteinizing hormone (LH) concentrations in many PCO patients suggest that a dysfunction may exist in the hypothalamic-pituitary axis with resultant ovarian endocrine changes.[1] On the other hand, increased peripheral concentrations and production rates of steroids as well as high levels of androgens in the ovarian vein suggest that a defect exists in ovarian steroidogenesis with secondary hypothalamic-pituitary dysfunction.[2]

0002-9378/79/090056+08$00.80/0 © 1979 The C. V. Mosby Co.

In vitro studies of ovaries from PCO patients have also produced conflicting results. Two defects in ovarian steroid enzymes have been demonstrated in some PCO patients: (1) An aromatase deficiency, which could explain the increased androgen to estrogen ratio, and (2) a 3-beta-hydroxysteroid dehydrogenase deficiency which would lead to increased production of Δ5 steroids such as dehydroepiandrosterone.[3] In contrast, other investigators have been unable to define defects of steroid enzymes in the polycystic ovary and have suggested that the increased androgen production results from an increase in the amount of ovarian tissue or from the hyperactivity of some ovarian cell types.[4]

In vitro experiments using isolated ovarian cells have provided important information regarding the steroidogenic potential of these ovarian endocrine compartments during different reproductive states.[5–7] In the present study, we have applied such in vitro techniques to the polycystic ovary for the purpose of determining whether chronic ovulation in the patient with PCO is related to deficiencies in the steroidogenic potential of the developmentally arrested midantral follicles in the polycystic ovary. To meaningfully interpret the data, we have performed similar experiments using cells from normal ovaries and used these data as a standard to which the observations from polycystic ovaries are compared.

Material and methods

Normal patients. Ovarian fragments were obtained from two patients undergoing laparotomy for nonendocrine reasons. Patient M. H. was a 30-year-old woman, gravida 1, para 1, who had experienced regular menses every 27 days prior to undergoing laparotomy at day 18 of the cycle. One ovary contained a fresh corpus luteum and was not used in this study. A wedge of tissue was removed from the opposite ovary, part of which was sent to the pathologists for tissue study and the remaining portion was placed in cold McCoy's 5a medium for in vitro studies. Patient S. B. was a 38-year-old woman, gravida 4, para 3, abortions 1, with regular menses occurring every 29 days. On day 8 of the menstrual cycle, the patient underwent hysterectomy and bilateral salpingo-oophorectomy for uterine leiomyomas. Portions of both ovaries were removed for experimental purposes and the remainder was fixed for histologic examination. The ovarian sections from both ovaries were judged to be normal.

Patients with PCO. Ovarian tissue was obtained from two patients with documented PCO. Patient M. D. was a 30-year-old woman, gravida 2, para 2, with obesity, hirsutism, and oligomenorrhea of increasing severity. Serum LH was 72 mIU/ml; follicle-stimulating hormone, (FSH) 6 mIU/ml; and testosterone concentration, 900 pg/ml (normal is between 300 and 750 pg/ml). 17-Ketosteroids were 10 mg/24 hours. Hysterectomy and bilateral salpingo-oophorectomy were performed for sterilization. Both ovaries were markedly enlarged (measuring 4 by 4 by 5 cm) and were surrounded by a thickened tunica albuginea with multiple graafian follicles.

Patient M. F. was a 33-year-old, nulligravid woman with documented PCO who underwent bilateral ovarian wedge resection after failing to respond to clomiphene citrate. Prior to surgery, levels of LH and FSH were 60 and 10 mIU/ml, respectively. Total serum testosterone was 850 pg/ml. Urinary 17-ketosteroids were 13 mg/24 hours. Both ovaries (measuring 4 by 4 by 5 cm) were covered with a thickened capsule and had numerous graafian follicles lining the subcortical surface.

Culture medium. Ovarian tissue was cultured in 6 ml of McCoy's 5a medium (modified, GIBCO), containing L-glutamine (2 mM, penicillin (100 U/ml), streptomycin sulfate (100 μg/ml), and 10% serum obtained from a patient with Sheehan's syndrome. This culture medium contained less than 20 pg/ml of progesterone (P), androstenedione (A), dehydroepiandrosterone (DHEA), testosterone (T), estrone (E_1), and estradiol (E_2). All cultures were maintained for 72 hours in a 95% air–5% carbon dioxide incubation at 37° C.

Each set of granulosa, theca, and medullary cultures was incubated either as a control or with one of the following agents: 1 IU/ml LH/FSH (Pergonal, Cutter Laboratories), 1 mM N^6O^2-dibutyryladenosine-3′:5″-cyclic monophosphoric acid (Bu_2cAMP, Sigma Chemicals), or 1.3 U/ml highly purified adrenocorticotropic hormone (ACTH) (Acthar, Armour Pharmaceutical Company). After 72 hours, the culture media were collected and stored at −20° C until analyzed for steroids by radioimmunoassay.

Granulosa cell cultures. Sets of five follicles (4 to 7 mm in diameter) from normal and polycystic ovaries were dissected intact from the ovarian tissue and then placed into separate dishes containing 5 ml of McCoy's medium. Each follicle was punctured with an iris knife and the granulosa cells were expressed into the media. By means of an orally controlled micropipette, the granulosa cells were transferred to a 15 ml conical centrifuge tube and spun at 250 × g for 10 minutes. The pellet was resuspended in a known volume of culture medium, and 100 μl of the cell suspension (50,000 cells) was added to appropriate 60 by 15 mm Falcon tissue culture dishes.

Theca and medullary cultures. After granulosa cells were removed, the remaining portions of the normal

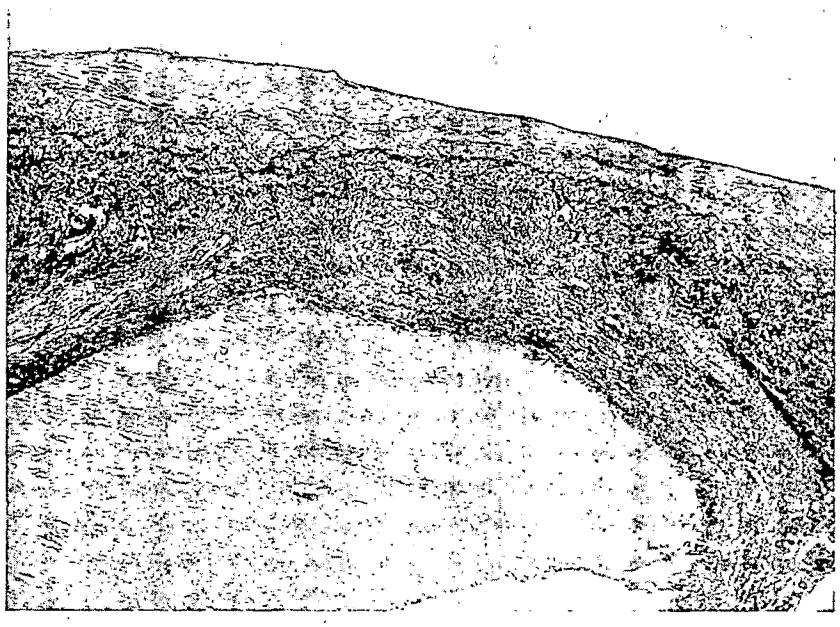

Fig. 1. Section of polycystic ovary, containing markedly thickened ovarian capsule with multiple subcapsular graafian follicles, with pronounced hyperplasia of the theca compartment.

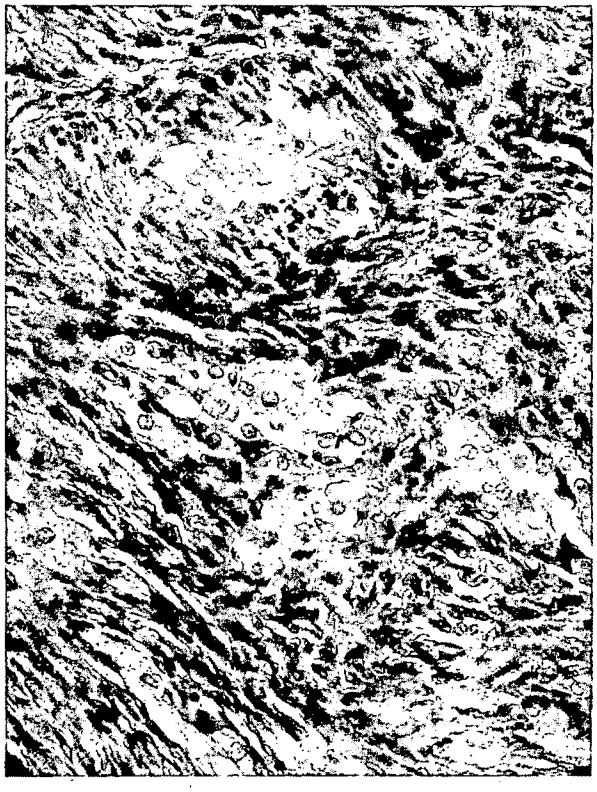

Fig. 2. Section of ovaries of Patient M. D., containing clusters of large epithelioid cells with eosinophilic cytoplasm scattered throughout the medullary stroma, which is suggestive of hyperthecosis.

and polycystic follicles were cut into four pieces and then scraped with an iris knife to remove the remaining granulosa cells from the basement laminae.[8] From this pool of normal and polycystic ovarian theca, three pieces (each 3 mm in diameter) were selected at random and placed into appropriate tissue culture dishes.

The medullary portions of the control and the polycystic ovaries were dissected free of cortical tissues and cut into pieces 3 mm in diameter. Ten pieces of control and polycystic medullary tissue were placed into appropriate culture dishes and incubated for 72 hours. All experiments (granulosa, theca, medullary tissue) were performed in quadruplicate.

Tissue study. Sections of normal and polycystic ovaries were obtained at the time of surgery. At the end of each experiment, representative cultures were prepared for tissue study as described previously.[5]

Steroid chromatography and radioimmunoassay. The chromatographic procedures and radioimmunoassays for progesterone, androstenedione, dehydroepiandrosterone, estrone, and estradiol-17β have been described previously.[9, 10] Dehydroepiandrosterone was measured according to the procedures described by Buster and Abraham.[11] Briefly, steroids were extracted from 1 ml of culture medium with 5 ml of fresh anhydrous diethyl ether. The aqueous phase was rapidly frozen with solid carbon dioxide and the organic phase was decanted and the ether evaporated under nitrogen. The residue was applied to Celite columns with

ethylene glycol as a stationary phase in 0.2, 0.2, and 0.3 ml of isooctane. The steroids measured were obtained from three elution fractions. Fraction I, containing progesterone and androstenedione, was eluted with 4.0 ml of isooctane. Fraction II, containing estrone and dehydroepiandrosterone, was eluted with 4.0 ml of 15% ethyl acetate in isooctane. Fraction III, which contained estradiol-17β, was eluted with 3.5 ml of 40% ethyl acetate in isooctane. The collection vials were evaporated to dryness under nitrogen and resuspended in 1.5 ml of 0.1M phosphate buffer, pH 7.0, containing 0.1% gelatin, and aliquots were taken for determination of recovery and radioimmunoassay.

The progesterone antibody demonstrated a cross-reactivity of 100% with progesterone, 35% with deoxycorticosterone, 7% with 20α-dihydroxyprogesterone, 5% with A and T, and less than 1% with other C_{21}, C_{19}, and C_{18} steroids. The antibody for A cross reacted 100% with A and 16% with DHEA but less than 1% with other steroids. The DHEA antibody cross reacted 100% with DHEA and DHEA sulfate and 12.5% with A. A nonspecific, total estrogen antibody was used to detect estrone but this antibody cross reacted less than 0.01% with C_{21} and C_{19} steroids. The estradiol antibody was more specific, cross reacting 100% with estradiol-17β, 3.0% with estrone and estriol, but less than 0.1% with other steroids. T in the media was measured directly (following extraction) using T antiserum (S No. 250, 11–bovine serum albumin) supplied by Dr. J. Bain. In addition to 100% cross-reactivity with testosterone, this antibody showed a high cross reaction with dihydrotestosterone (72%) but did not cross react (less than 1%) with other C_{18}, C_{19}, and C_{21} steroids.

The interassay coefficient of variation for all steroids was less than 17% and the intra-assay coefficient of variation was less than 9%.

§Nondetectable.

cated the presence of a markedly thickened ovarian capsule with multiple subcapsular graafian follicles (4 to 7 mm in diameter), with pronounced hyperplasia of the theca compartment (Fig. 1). Ovaries of Patient M. D., but not Patient M. F., contained clusters of large epithelioid cells with eosinophilic cytoplasm scattered throughout the medullary stroma, which is suggestive of hyperthecosis (Fig. 2). The ovaries of both control patients were grossly and microscopically normal. In Patient M. H., the left ovary contained a fresh corpus luteum.

In vitro tissue study. The granulosa cells from both normal and polycystic ovaries attached to the culture dish within the first 24 hours in vitro and grew primarily as colonies of epithelial cells. After 72 hours in vitro, the normal and polycystic granulosa cells treated with gonadotropins and Bu_2cAMP underwent luteinization and developed large numbers of osmiophilic lipid droplets, and control and ACTH-treated granulosa cells appeared as typical nonluteinized cells.

The morphologic and cytologic characteristics of normal and polycystic theca tissue in vitro are similar to those reported in organ cultures of human,[6] rabbit,[12] and hamster[7] theca elements. In the theca cultures, the explants had attached to the culture dish by 3 days and fibroblasts and epithelial cells were migrating from the explants. No obvious differences were observed between control and hormone-treated explants. Similar results were obtained in the cultures of normal and polycystic medullary tissue.

Steroid production in vitro. The steroids secreted into the media by granulosa, theca, and medullary tissue of normal and polycystic ovaries are presented in Tables I, II, and III, respectively.

As shown in Table I, control cultures of granulosa cells from normal follicles 4 to 7 mm in diameter of patients during the follicular and luteal phases of the cycle spontaneously secreted low levels of progesterone. In both cases, the production of progesterone by the normal granulosa cells was stimulated approximately tenfold by FSH/LH or Bu_2cAMP, but ACTH was without effect. Little, if any, A, DHEA, T, E_1, or E_2

accummulated in the media of any normal granulosa cell culture. In a parallel set of experiments (Table I) similar results were obtained with cultured granulosa cells from 4 to 7 mm follicles of polycystic ovaries. The only obvious difference between the normal and polycystic granulosa cell cultures was an apparent ACTH stimulation of progesterone secretion by the polycystic granulosa cells.

Table II shows the steroid hormones produced by the isolated theca tissue obtained from follicles 4 to 7 mm in diameter of normal and polycystic ovaries. The control pieces of normal theca secreted large amounts of A, some P and T, but little if any E_1 or E_2. Addition of LH/FSH caused a marked stimulation in A and P secretion by theca from Patient M. H. but was less effective in stimulating the production of these hormones in the theca from Patient S. B. Addition of Bu_2cAMP or ACTH in the normal theca cultures produced stimulatory effects. A slight stimulatory effect of LH/FSH upon estrogen production by the theca of both the normal patients was observed. In general, similar results were obtained with isolated theca fragments obtained from 4 to 7 mm follicles of patients with PCO. The principal steroids secreted by polycystic theca were A and P and the production of these steroids was stimulated by LH/FSH and/or Bu_2cAMP but not by ACTH. Although low levels of estrogens were detected in the polycystic theca cultures, no stimulatory effect of estrogen secretion was obtained by the added trophic agents.

As shown in Table III, control and experimentally treated cultures of medullary tissue from both normal and polycystic ovaries secreted very little, if any, steroids in vitro. However, in one case, the medullary tissue from Patient M. D. with hyperthecosis secreted relatively large amounts of all steroids (except estrogens) during the 3 day incubation and the production of these steroids appeared to be stimulated slightly by Bu_2cAMP but not by LH/FSH or ACTH.

Comment

These observations have shown that there is no obvious difference between the de novo steroidogenic potentials of the endocrine cells (isolated theca and granu-

losa cells) of the midantral follicles (4 to 7 mm in diameter) of normal and polycystic ovaries. During a 3 day incubation in the presence and absence of trophic agents, the steroidogenic profiles of the normal and polycystic follicular tissues were found to be similar, both qualitatively and quantitatively. On the basis of these findings, it would seem that the cessation of follicle growth and maturation in the polycystic ovaries is not caused by an obvious deficiency in the development of the endocrine potentials of the granulosa and theca cells. Therefore, these findings indicate that follicle development up to the midantral stage is probably normal in the polycystic ovary and suggest that the cessation of follicle maturation at the midantral stage may not be related to an inherent developmental abnormality in the theca and granulosa cells of the polycystic follicles. Since FSH has been shown to be essential for the continuation of normal follicle maturation to the preovulatory stage,[13] it is possible that defective secretion of FSH in patients with PCO is the principal cause of the cessation of follicle development in the polycystic ovary.

The granulosa cells from midantral follicles of both normal and polycystic ovaries undergo morphologic luteinization and secrete increased amounts of P in response to gonadotropins and Bu_2cAMP in vitro. On a per-cell basis, these normal and polycystic granulosa cells secreted comparable amounts of progestin during the 3 day incubation period. As expected, none of the normal and polycystic granulosa cell cultures secreted significant amounts of androgens and estrogens in vitro.[8, 13, 14] The absence of a detectable effect of exogenous ACTH upon normal and polycystic granulosa cell function suggests that ACTH may not modulate human granulosa cell function; however, more experiments are necessary to establish this with certainty. The present morphologic and biochemical findings with cultured human granulosa cells are consistent with previous observations on the behavior of undifferentiated human granulosa cells from medium-size antral follicles.[15] Based on our present findings, it seems likely that the developmental state of the granulosa cells in the midantral follicles of polycystic ovaries is similar to that of normal granulosa cells in medium-size follicles of normal ovaries, at least in terms of their ability to respond to gonadotropins and secrete P in vitro.

The theca tissue from treated and control medium follicles (4 to 7 mm in diameter) of normal and polycystic ovaries secreted primarily A during the 3 day culture period. This finding is consistent with previous observations that the theca interna is principally an androgen-producing tissue.[12–14] Although it was not possible in the present experiments to determine the exact number of theca interstitial cells in any of the cultured theca explants, it is of interest that, in general, the androgenic capacity was quite similar in cultures of polycystic and normal theca. Although one must be cautious, the present data suggest that the capacity of the polycystic and normal theca of midantral follicles to secrete A in vitro is comparable. The androgen production by normal theca cells was stimulated following treatment with gonadotropin and/or Bu_2cAMP; however, the data were variable. In general, this result is consistent with previous reports that androgen production by theca cells is stimulated by LH and cyclic adenosine monophosphate.[12] It is of interest that the control gonadotropin-treated cells of both normal and polycystic theca produced very little, if any, E_1 and E_2 during the 3 day incubation. This finding is consistent with previous studies which have shown that the theca compartment has a relatively limited capacity to aromatize androgen into estrogen in vitro.[12, 14, 16] Therefore, our present in vitro results are not inconsistent with the current two-cell theory for estrogen production by the follicle in which the theca cells produce androgens which diffuse into the granulosa cells where they are aromatized into estrogen.[16]

In our experiment, the only obvious difference observed between the steroidogenic potentials of the endocrine compartments of the normal and polycystic ovaries was in the steroidogenic response of the medullary tissue obtained from Patient M. D. In this study, the isolated polycystic medullary tissue secreted levels of androgens and P higher than those of normal medullary tissue. Clusters of steroid-secreting–like cells (suggestive of hyperthecosis) were found in the medullary tissue of the polycystic ovary from Patient M. D. Although the nature of the steroid-secreting cells in the medulla of polycystic ovaries is unknown, it appears from our data that such cells are predominantly androgen producing and therefore resemble, endocrinologically, the steroid-secreting cells found in the theca interna.

Recently, evidence has been reported for the existence of 11β-hydroxylase activity[17] and glucocorticoid production[18] in polycystic ovaries. This observation raises the possibility that adrenal-like steroid-secreting cells exist in the medulla of some polycystic ovaries with hyperthecosis. In view of the possibility that glucucorticoid production may be the abnormality of some polycystic ovaries with hyperthecosis, we investigated the effects of ACTH on the cellular compartments of the polycystic ovaries and compared the results with those obtained from normal ovarian tissue. No consistent trophic effect of ACTH was demonstrated. The sporadic significant differences between some steroids

in response to ACTH and their control cultures are likely due to minimal gonadotropin contamination of the ACTH preparation or small variation in tissue size.

In summary, our results suggest that the steroidogenic capacity of isolated granulosa and theca cells of midantral follicles (4 to 7 mm in diameter) of polycystic ovaries is comparable to that of normal granulosa and theca cells from midantral follicles of normal ovaries. Therefore, these findings strongly suggest that the midantral follicles of polycystic ovaries are normal. If this is indeed true, then chronic anovulation in the patient with polycystic ovaries may not be causally connected with an inherent endocrine abnormality in the theca and granulosa cells of the developing follicle in the polycystic ovary.

Lower esophageal sphincter pressure during the normal menstrual cycle

DAVID H. VAN THIEL, M.D.*
JUDITH S. GAVALER, B.A.
JOHN F. STREMPLE, M.D.
Pittsburgh, Pennsylvania

Lower esophageal sphincter pressure (LESP), basal gastric pH, and plasma levels of gastrin, estradiol, and progesterone were determined in ten women known to have normal menstrual cycles. All determinations were performed both during the follicular phase (Days 2 to 8) and during the luteal phase (Days 20 to 30). In addition, an intraluminal pH probe placed 5 cm. above the lower esophageal sphincter was used to test for the presence of acid reflux in response to three provocative procedures. LESP during the follicular phase was 19.0 ± 1.5 mm. Hg (mean ± S.E.M.) and during the luteal phase 16.5 ± 1.3 mm. Hg ($p < 0.01$). Basal gastric pH and plasma gastrin levels were similar at both times. Plasma estradiol in the follicular phase (76.1 ± 7.0 pg. per milliliter) increased twofold during the luteal phase (159.0 ± 6.0) ($p < 0.01$). Plasma progesterone increased from a level of 1.5 ± 0.8 ng. per milliliter during the follicular phase to 19.2 ± 4.2 during the luteal phase. Coincident with these changes in LESP and increases in steroid levels, acid reflux was detected in five women during the luteal phase but was present in only one during the follicular phase. (AM. J. OBSTET. GYNECOL. 134:64, 1979.)

PREGNANT WOMEN experience a variety of upper gastrointestinal complaints. These include heartburn, nausea, and early satiety which are commonly ascribed to the syndrome of "morning sickness." Despite their frequency the pathophysiologic basis for the increased incidence of these complaints during pregnancy is poorly understood.

Although the regulating role of estrogens and progesterone in regard to the contractile and bioelectrical activities of myometrium[1, 2] have been studied in detail, remarkably little has been studied relative to the effect of these sex steroids on gastrointestinal muscle.

Relative to this question, recent in vitro studies have shown progesterone, but not estrogens, to reduce the tension which can be achieved in smooth muscle strips from the lower esophageal sphincter of the opossum in response to electrical, neurotransmitter and gastrointestinal hormonal stimuli.[3, 4] Moreover, recent studies in vivo have suggested a role for either progesterone alone or the combination of a potent estrogen followed by progesterone given sequentially as being responsible for a reduction in lower esophageal sphincter pressure (LESP) in pseudopregnant women and animals.[5, 7]

As a direct extension of these earlier studies, we have asked the question, might not the same sequential changes in plasma levels of steroids which occur during the normal menstrual cycle, albeit to a much lesser degree than during pregnancy, reduce LESP of women during the luteal phase as compared to the follicular phase of the menstrual cycle. The purpose of the present study was therefore to: (1) compare LESP in normal menstruating women during the follicular phase (Days 2 to 8) and during the luteal phase (Days 20 to 30) of the menstrual cycle, and (2) determine whether changes in plasma sex steroid levels occurring as a result of ovulation might correlate with measured changes in LESP.

Methods

Volunteers studied. Ten young adult normally menstruating women with a mean age of 24.6 ± 1.8 (S.E.M.) years (range 20 to 37) and known not to have been using oral contraceptives within a period of at least three months prior to their participation in this study were evaluated. Nine of the ten volunteers studied denied any prior history of symptomatic heartburn or other gastrointestinal disease. Before each study, informed consent was obtained from each volunteer. Moreover, before the study was initiated, approval was obtained from the Human Research Review Committee of the University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania.

Intraluminal pressure measurement. All studies were performed in the Gastrointestinal Laboratory of the Presbyterian–University Hospital of the University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania. All volunteers were studied in a supine position. Three water-filled polyvinyl tubes, 1.4 mm. in internal diameter, were combined with pH electrode as a single manometric tube. The tube was inserted into the stomach and slowly withdrawn at 1 cm. intervals with initial identification of the LES as an area of localized high pressure which relaxes with swallowing. The side openings of the pressure-transmitting catheters measured 1.3 mm. in diameter and were placed at 5 cm. intervals. Intraluminal pressure was measured as pressure transmitted via these water-filled catheters to external pressure transducers (Statham 18429P 23AC) and recorded on a multichannel polygraph recorder (Grass 29349B). Each catheter was infused with distilled water at a constant rate of 0.5 ml. per minute. Sphincter pressure utilized for analysis was recorded in millimeters of mercury at the end of inspiration using the rapid pull through technique (0.5 cm. per second) with intragastric pressure used as zero reference. The mean of three individual measurements of LESP made during a single pull through, and repeated for a total of three separate complete pull throughs, was used for statistical comparisons. At the perfusion flow rate used, the performance characteristics of the manometry equipment used in our laboratory detect changes in esophageal pressure at a rate of 70 mm. Hg per second.

Procedures. All studies were performed in the morning after an overnight fast. Each volunteer was studied twice, once in the follicular phase (Days 2 to 8) and once in the luteal phase (Days 20 to 30) of one or two consecutive menstrual cycles. Day 1 was defined as the first day of menstrual bleeding. Six volunteers were first studied in the follicular phase and subsequently studied in the luteal phase, while four volunteers were first studied in the luteal phase and subsequently studied in the follicular phase with the order being determined by the convenience of the volunteer. The investigator was blinded as to the sequence of the studies for a given volunteer until completion of both studies. Before each study, 20 c.c. of blood was drawn for determination of plasma levels of gastrin, estradiol, and progesterone. Basal gastric pH was recorded at the start of each motility study.

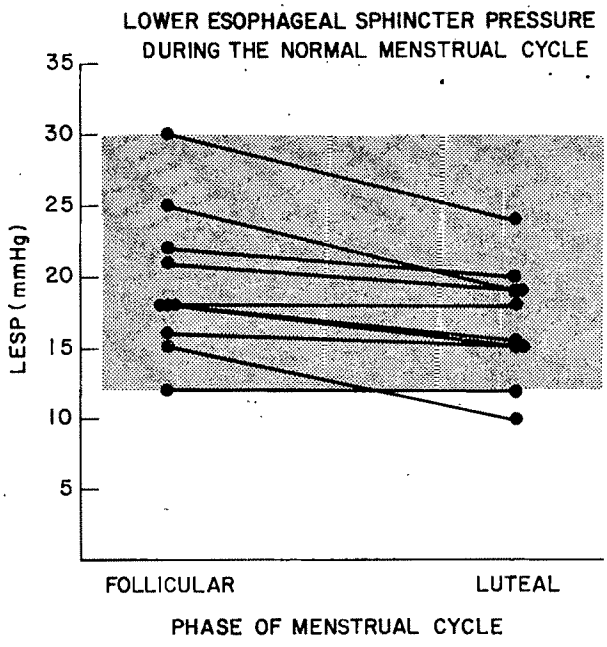

Fig. 1. Lower esophageal sphincter pressure during the follicular and luteal phases of the female volunteers studied. The solid lines connect the pressures for an individual volunteer. The shaded area is the range of values for normal women in our laboratory without attention to the menstrual cycle.

The presence of reflux was evaluated in each volunteer at the end of each study. Reflux was considered present when following the instillation of 100 c.c. of 0.1N HCl into the stomach, acid (pH <4.0) was detected by an intraluminal pH probe positioned 5 cm. above the LES with the subject in the supine position during any of the following three provocative procedures: (1) sniffing against a closed nose and mouth, (2) prolonged Valsalva maneuver, and/or (3) prolonged straight leg raising.

Plasma gastrin. Blood for plasma gastrin was obtained from each fasting volunteer before each study. Plasma was immediately separated and stored frozen at −20° C. until assayed. All gastrin determinations were performed in duplicate in a single assay by a radioimmunoassay method.[8] The sensitivity of the gastrin assay was 10 pg. per milliliter with an intra-assay variation of less than ten per cent.

Table I. Plasma gastrin, estradiol, and progesterone levels in the volunteers studied during the two phases of the menstrual cycle

	Follicular phase	*Luteal phase*
Gastrin (pg./ml.)	76 ± 3.0	81 ± 4.0
Estradiol (pg./ml.)	76.1 ± 7.0*	159.0 ± 6.0
Progesterone (ng./ml.)	1.5 ± 0.8*	19.2 ± 4.2

*$p < 0.01$.

Plasma steroids. Fasting blood for plasma estradiol and progesterone was obtained from each fasting volunteer before each study. Plasma was immediately separated and stored frozen at −20° C. until assayed using radioimmunoassay methods.[9, 10] All samples were run in duplicate in a single assay thus avoiding any interassay variation. Intra-assay variation of the radioimmunoassay for each steroid was less than ten per cent. The detection limit of the estradiol assay was 1.0 pg. and the detection limit of the progesterone assay was 10 pg.

Interpretation of data. All manometric tracings and seum samples were coded and read or analyzed blindly after all the studies were completed. The Student t test for paired data was used for statistical analysis.

Results

The sphincter pressures recorded during the follicular and luteal phases of the menstrual cycle for each patient are shown in Fig. 1. The mean pressure ± S.E.M. during the follicular phase was 19.0 ± 1.5 mm. Hg with a range from 12.0 to 30.0 mm. Hg. The mean pressure during the luteal phase was 16.5 ± 1.3 mm. Hg with a range from 10.0 to 26.0 mm. Hg. The difference in LESP recorded between the follicular and luteal phase of these ten volunteers was significantly different at the $p < 0.01$ level. All pressures but one were within the range of values for normal women without regard to menstrual cycle changes in our laboratory. The only pressure recorded outside the normal range for LES pressure was obtained during the luteal phase of the individual volunteer's menstrual cycle. Unprovoked symptomatic and pH probe positive reflux was present in only one volunteer studied during the follicular phase (the only volunteer who had an LESP below the normal range). The other nine volunteers failed to demonstrate reflux under either basal conditions or in response to the three provocative stimuli utilized. During the luteal phase symptomatic reflux was present in the same volunteer who had symptoms during the follicular phase but was also pH probe positive in four additional volunteers in response to one or more of the three provocative stimuli but not under basal unprovoked conditions.

Mean basal gastric pH during the follicular phase (2.9 ± 0.2; range 2.0 to 4.0) and luteal phase 3.3 ± 0.3; range, 2.3 to 5.2) of the menstrual cycles did not differ. Mean fasting gastrin concentrations during each of the phases of the menstrual cycle are shown in Table I. Similarly, mean fasting plasma estradiol and progesterone levels during the two phases of the menstrual cycle are shown in Table I. The mean progesterone level during the follicular phase was 1.5 ± 0.8 ng. per milliliter while a tenfold mean increase was observed during the luteal phase (19.2 ± 4.2 ng. per milliliter), when LESP was observed to decline.

Comment

This study documents a small but statistically significant reduction in LESP in normal women during the luteal phase of the menstrual cycle compared to LESP recorded in the follicular phase of these same volunteers. Coincident with the observed reduction in LESP, and as a direct consequence of ovulation, plasma progesterone levels were observed to increase during the luteal phase from levels observed during the follicular phase. Thus, the changes in progesterone levels and in LESP which were observed in this study, although not shown to be directly related, are consistent with previous reports in which progesterone has been shown to directly reduce LESP[3, 4, 7] in vitro. Moreover, these results are consistent with those previously reported in women[4, 6] and animals[7] which demonstrate that coincident with a sequential estrogen-progesterone exposure such as occurs during pregnancy and with the use of sequential oral contraceptive agents, LESP declines.

The observed decline in LESP of these normal volunteers during the luteal phase compared to LESP during the follicular phase, however, was small. Thus, only one of the subjects studied had an LESP recorded outside and below the range for normal. It is not surprising, therefore, that the frequency of symptomatic heartburn has not been reported previously to be increased in women during the luteal phase compared to the follicular phase of the menstrual cycle. When provocative tests were utilized to evaluate for the presence of stress-induced reflux, however, five of the ten women we studied had pH probe–positive reflux (only one was symptomatic) during the luteal phase compared to only one during the follicular phase. It is not unreasonable to assume, therefore, that the small but statistically significant reduction in LESP observed during the luteal phase of the menstrual cycle in asymp-

tomatic women is only clinically important when it occurs in conjunction with one or more other factors that also reduce LESP or stress the competence of the LES. The combined effect of several such factors acting together presumably might reduce LESP enough to produce symptomatic heartburn in the luteal phase more frequently than in the follicular phase of susceptible women. Consistent with such a formulation is our unpublished observation that female medical students experience symptomatic heartburn more commonly during the latter half of their menstrual cycles (Days 15 to 28, i.e., luteal phase) than during the immediate postmenstrual period (follicular phase). Specifically, during the preceeding three years 25 female medical students at the University of Pittsburgh who were not using oral contraceptives agreed to keep a diary of their menstrual cycles and when they experienced symptomatic heartburn. As a result of such cooperation, we have been able to observe these women during a total of 405 complete menstrual cycles. Arbitrarily dividing each menstrual cycle into follicular phase (Days 1 to 14) and luteal phase (Days 14 to first day of vaginal bleeding) and then assigning each of the 135 documented episodes of heartburn to one or the other two menstrual cycle phases, we found a significant preponderance of symptomatic heartburn episodes during the luteal phase ($\psi^2 = 88.8889$; $p < 0.001$) as compared to the follicular phase. The failure to detect a significant difference in basal gastric pH and plasma gastrin levels during the course of this study as well as in previous studies[5, 6] tends to negate a role for either of these two factors in the genesis of the observed LESP reduction.

In summary, these studies demonstrate that: (1) Basal resting LESP during the luteal phase of the menstrual cycle is reduced in women relative to LESP measurements recorded in the follicular phase, and (2) changes in basal gastric pH and plasma gastrin levels cannot account for this observed decline in LESP during the luteal phase as compared to the follicular phase.

To determine the microbiologic etiology of acute salpingitis, laparoscopy was used in 26 patients to obtain specimens for a variety of microorganisms directly from the fallopian tube. Simultaneous culdocentesis was performed to obtain peritoneal fluid for microbiologic analysis. A variety of microorganisms were isolated from the fallopian tubes and cul-de-sac aspirate. However, the organisms isolated from the fallopian tube were not consistent with the cul-de-sac isolates. It appears that direct culture from the fallopian tube may be necessary to determine the microbiologic etiology and pathogenesis of acute salpingitis. *N. gonorrhoeae* was isolated from the cul-de-sac in 32 per cent of cases and the fallopian tube in 19 per cent. In patients with endocervical gonorrhea the gonococcus was isolated from the fallopian tube n 38.5 per cent of cases. Aerobic and/or anaerobic bacteria were present in the cul-de-sac aspirate in 46 per cent of patients and in the fallopian tube in 38 per cent. (AM. J. OBSTET. GYNECOL. 134:68, 1979.)

ACUTE SALPINGITIS remains a frequent disease in young women with significant implications for future fertility.[1–4] Concomitant with the current epidemic of sexually transmitted diseases[5] and increased usage of intrauterine contraceptive devices,[6, 7] the incidence of acute salpingitis has increased. It has been estimated that 500,000 to 700,000 women per year in the United States are treated for acute salpingitis.[7, 8]

The goals in management of acute salpingitis are prevention of infertility and the chronic residuals of infection, such as pelvic adhesions, hydro- or pyosalpinx, tuboovarian abscess, pelvic pain, and dyspareurnia, which often lead to surgical intervention.

To attain these goals, treatment regimens based on knowledge of the microbiologic etiology of acute salpingitis must be developed.

Until recently, the majority of attempts to determine the etiology of acute salpingitis have relied on isolation of microorganisms from the endocervix. With this methodology, acute salpingitis was divided into gonococcal and nongonococcal cases based solely on the presence or absence of *Neisseria gonorrhoeae* in the endocervix. However, recent investigations with culdocentesis and/or laparoscopy to obtain peritoneal fluid and tubal exudate have shown that the occurrence of pathogenic microorganisms in the cervix is not proof that such microorganisms are associated with tubal inflammatory disease.[3, 4, 9–13]

In an attempt to determine the microbiologic etiology of acute salpingitis, the present study utilizing laparoscopy to visually confirm the diagnosis and to obtain culture specimens directly from fallopian tube exudate was undertaken. Additionally, simultaneous culdocentesis was performed to determine the appropriateness of culdocentesis specimens in identifying pathogenic microorganisms involved in acute salpingitis.

Material and methods

Study population. Women presenting to the San Francisco General Hospital Emergency Room with a diagnosis of acute salpingitis requiring hospitalization were entered into the study after appropriate informed consent was obtained. A tentative diagnosis of acute salpingitis was based on the following clinical criteria: (1) history of current lower abdominal pain, (2) presence of lower abdominal tenderness, (3) presence of cervical motion tenderness, (4) presence of adnexal tenderness, (5) oral temperature greater than 100.4° F., and/or (6) leukocytosis greater than 10,500 per cubic millimeter. At least four of these criteria had to be present for inclusion in the study.

Twenty-nine women were initially entered into the study. At the time of laparoscopy, the diagnosis of acute salpingitis was confirmed in 26 women. The remaining three patients (one case each of appendicitis, ectopic pregnancy, and bowel obstruction) were dropped from the study. Visual confirmation was based on the presence of: (1) purulent exudate from the fimbriated end or serosal surface of the fallopian tube, (2) erythema of fallopian tube, (3) edema and swelling of fallopian tube, and/or (4) inflammatory mass, such as pyosalpinx or tuboovarian abscess, involving the fallopian tube.

After the diagnosis of acute salpingitis was confirmed, microbiologic studies were performed on specimens from: (1) the endocervix, (2) exudate from the fallopian tube obtained at the time of laparoscopy, and (3) peritoneal fluid obtained via culdocentesis. The endocervix was cultured for *Neisseria gonorrhoeae, Chlamydia trachomatis,* Herpesvirus, *Mycoplasma hominis,* and *Ureaplasma urealyticum.* In addition to these microorganisms, specimens from the fallopian tube and culdocentesis fluid were cultured for aerobic and anaerobic bacterial.

Culture specimens for *N. gonorrhoeae* from the cervical os, culdocentesis, and laparoscopy were directly plated on NYC medium[14] and chocolate agar made with GC agar base, hemoglobin, and Isovitalex.* The plates were transported directly to the laboratory for incubation. Specimens from the endocervix, culdocentesis, and laparoscopy were cultured for *M. hominis* and *Ureaplasma urealyticum* by direct inoculation into NYC agar. A portion of the specimen was transported to the laboratory in mycoplasma A3X broth[15] and was inoculated into urea broth and A7 differential agar medium for mycoplasmas.[16, 17]

Culture specimens for chlamydia were put into Eagle's minimum essential medium and refrigerated at 4° C. when the specimen was not processed immediately. Iododeoxyuridine-treated monolayers of McCoy cells were inoculated with the specimen by centrifugation; the culture medium was replaced, and the cells were cultured 65 hours. The cells were examined with iodine and Giemsa stains for typical chlamydial inclusions.[18]

Culture specimens for herpesvirus were put into the same supplemented Eagle's minimum essential medium described for chlamydia. Monolayers of Vero kidney cells were inoculated with the specimen in the above medium and incubated.[18, 19]

Specimens for aerobic and anaerobic bacteria were freed of air bubbles and injected into anaerobic collection tubes containing oxygen-free carbon dioxide and rezazurin indicator. The specimens were taken directly to the laboratory by a member of the surgical team for immediate processing. The anaerobic cultures were set up in an anaerobic glove box. The following media were inoculated for cultivation of anaerobic bacteria: (1) Brucella agar medium* with 5 per cent defibrinated sheep blood, 100 μg per milliliter of vitamin K, and 5 μg of hemin; (2) the same supplemented agar medium containing 10 μg per milliliter of kanamycin; (3) thioglycollate 135C† supplemented as above with vitamin K and hemin; (4) prereduced, anaerobically sterilized chopped meat medium. Aerobic bacteria were cultured on trypticase soy agar with 5 per cent defibrinated sheep blood and MacConkey's agar.† Media were incubated at 35° C.

When there was insufficient exudate for direct aspiration, sterile, expandable plastic sponges‡ were introduced through the laparoscope and allowed to expand with fluid. The sponges were then placed into a 2.5 ml. dilution blank of prereduced, anaerobically sterilized

peptone yeast extract broth.[20] This volume was then divided and distributed into the various transport media.

Results

The age range in the study patients was 18 to 35 years, with a mean age of 24. There were 14 white, 10 black, and 2 Latin American patients included in the study. Seventeen patients (65.5 per cent) reported having been pregnant at least once and 14 patients were para 1 or greater. This was the initial episode of salpingitis in seven (27 per cent) women and the third or more episode in nine (34.5 per cent) patients.

In Table I, the general distribution of microorganisms isolated from the various culture sites is portrayed. Although *N. gonorrhoeae* was isolated from the endocervix in 13 (50 per cent) of the study group, it was isolated from the culdocentesis specimen in only eight (31 per cent) patients and from the fallopian tube in five (19 per cent). *N. gonorrhoeae* was the sole isolate from the endocervix of one patient, the culdocentesis aspirate in four patients, and the fallopian tube in four. In none of the patients without *N. gonorrhoeae* detected in the endocervix was this organism present in the fallopian tube or culdocentesis aspirate. In the 13 patients with *N. gonorrhoeae* isolated from the endocervix (Table II), the gonococcus was isolated from the culdocentesis aspirate in eight (61 per cent) patients, and from the fallopian tube in five (38.5 per cent).

Genital mycoplasma strains were frequently isolated from the endocervix of these salpingitis patients. *M. hominis* was isolated from the endocervix in 19 cases and *Ureaplasma urealyticum* in 14 cases. In nine (35 per cent) instances, mycoplasma strains were the sole isolate from the endocervix (Table I). Despite such frequent presence in the endocervix, mycoplasma strains were relatively infrequent isolates from the upper genital tract (Table II). *M. hominis* was isolated from the culdocentesis aspirate in one patient and from the fallopian tube in none of the cases. *Ureaplasma urealyticum* was found in the culdocentesis aspirate of four and in the fallopian tube of a single case. However, *ureaplasma urealyticum* was the sole isolate from the fallopian tube in only one patient and from the culdocentesis aspirates in two of 26 patients. *M. hominis* was never the sole isolate from the fallopian tube or culdocentesis aspirate. *C. trachomatis* was isolated from the endocervix in two patients. *C. trachomatis* was not isolated from the culdocentesis aspirate and/or the fallopian tube in any cases (Table I). However, 18 (69 per cent) of patients had a positive serologic titer against *C. trachomatis*. Herpesvirus hominis was not isolated from the endocervix, culdocentesis aspirate, or fallopian tube in any patients.

Aerobic bacteria as the sole isolates were found in the fallopian tube of four patients and in the culdocentesis aspirate of four patients (Table I). Anaerobic bacteria were the sole isolates from the fallopian tube in one case and the culdocentesis aspirate in one case. Mixed aerobic and anaerobic bacteria were identified in the fallopian tube in four cases and the culdocentesis aspirate in three cases. Mixed aerobic and anaerobic bacteria in association with *N. gonorrhoeae* were isolated from the fallopian tube in one patient and the culdocentesis aspirate in four patients. Over all, anaerobic bacteria were isolated from the fallopian tube in six (23 per cent) patients and from the culdocentesis aspirate in seven (27 per cent) patients. Aerobic bacteria (with or without *N. gonorrhoeae*) were isolated from the fallopian tube in nine (34.5 per cent) patients and the culdocentesis aspirate in 10 (38.5 per cent).

The bacterial isolates (not gonococcus) obtained from the fallopian tube and/or culdocentesis aspirate are listed in Table III. *E. coli*, Group B beta-hemolytic streptococcus, corynebacterium vaginale, alpha streptococcus, and *H. influenzae* were the most common aerobic isolates. Peptococcus, Peptostreptococcus, Bacteroides sp., and Clostridium were the most commonly isolated anaerobic organisms.

Comment

Classically, acute salpingitis has been divided into gonococcal and nongonococcal salpingitis. This classification has been based on the isolation of *N. gonorrhoeae* from the endocervix. The 50 per cent isolation rate for *N. gonorrhoeae* from the endocervix in this study is con-

sistent with previous investigations, in which isolation of *N. gonorrhoeae* from the endocervix was reported in 33 to 80 per cent of patients with acute salpingitis.[1, 4, 8, 10, 11, 13, 21, 22]

However, concern has been raised that the presence of pathogenic bacteria in the endocervix is not absolute proof that such bacteria are associated with upper genital tract infection. Many of the aerobic and anaerobic bacteria associated with pelvic infections reside in the cervix and vagina as part of the normal flora.[23] Utilization of culdocentesis, laparoscopy, and laparotomy to obtain culture specimens from peritoneal fluid and/or tubal exudate have shown an inconsistent and poor correlation between the cervical and intra-abdominal cultures. The recovery of *N. gonorrhoeae* from tubal exudate and/or peritoneal fluid in patients with acute salpingitis and endocervical gonorrhea has been reported in from 4 to 70 per cent of the patients.[9–11, 13, 24–28] In this study, we were able to isolate *N. gonorrhoeae* from the cul-de-sac aspirate in 61 per cent of the patients in whom *N. gonorrhoeae* had been cultured from the endocervix.

We were able to isolate *N. gonorrhoeae* from the fallopian tube in 19 per cent of patients with visually confirmed salpingitis. In patients with *N. gonorrhoeae* isolated from the endocervix, 38.5 per cent had *N. gonorrhoeae* isolated from fallopian tube exudate.

Like other investigators,[13, 28] we were able to frequently isolate *M. hominis* and *Ureaplasma urealyticum* from the endocervix. However, these studies reported a low (2 to 8 per cent) tubal isolation rate of genital mycoplasma; similarly, we were able to isolate *M. hominis* from the fallopian tube in none of our patients and *Urea-plasma urealyticum* in one of 14 patients with endocervical isolation of *Ureaplasma urealyticum*. Mardh and co-workers[12] were able to isolate *C. trachomatis* from the cervix in 19 of 53 patients (36 per cent) with acute salpingitis and from the fallopian tube in six of 20 tubal specimens obtained. Of the seven patients from whom *C. trachomatis* was isolated from the cervix and from whom tubal specimens were also obtained, *C. trachomatis* was recovered from the fallopian tube in six (86 per cent). In the present study, *C. trachomatis* was isolated from the endocervix in two of 26 patients; we were unable to isolate *C. trachomatis* from any of the Fallopian tube specimens. Although *C. trachomatis* has been implicated in Sweden[12] as a significant pathogen in salpingitis, its role in salpingitis in the United States awaits confirmation. In addition, the question of whether *C. trachomatis* is present as a colonizer or actually produces tissue destruction (alone or in synergy with other microorganisms) must be resolved.

Recent microbiologic investigations of peritoneal fluid obtained via culdocentesis in patients with salpingitis have disclosed the presence of a variety of aerobic and anaerobic bacteria (Tables IV and V).

In the present study, *N. gonorrhoeae,* as the sole isolate or in combination with other microorganisms, was present in eight of 26 (31 per cent) patients. Aerobic and/or anaerobic bacteria were present in the culdocentesis aspirates of 12 (46 per cent) patients.

The assumption has been made[3, 9–11, 13] that bacteriologic evaluation of peritoneal fluid specimens obtained via culdocentesis is an accurate reflection of the microorganisms present in the fallopian tube of salpingitis patients. However, the discrepancies noted in Tables I, II, and III between culdocentesis isolates and fallopian tube isolates raises serious concern over such an assumption. The presence of aerobic and/or anaerobic bacteria (Table III) in the cul-de-sac specimens that were not isolated from the fallopian tube specimens requires further investigation to evaluate the reliability of culdocentesis as an appropriate method of specimen collection for determining the microbiologic etiology of acute salpingitis. One possible explanation for this discrepancy may be contamination of the culdocentesis aspirate with microorganisms from the vaginal flora. Another source for this difference might be that with pelvic peritonitis and an inflammatory reaction in the bowel wall the bowel wall defense mechanisms may be altered to allow diffusion of the bowel flora into the peritoneal cavity. It is also

possible that as we enter additional patients into our study culdocentesis specimens may be shown to reflect the microorganisms found in the fallopian tube specimens. Until further investigations to compare culdocentesis aspirates and direct fallopian tube specimens are performed, we believe that caution should be used in interpreting the bacteriologic results from specimens obtained by culdocentesis. If additional studies confirm the discrepancy noted in our investigation, then only specimens obtained directly from the fallopian tube will be appropriate to identify the microbiologic etiology of acute salpingitis.

Although the isolation of bacteria from the fallopian tubes and culdocentesis aspirates revealed significant differences, the fallopian tubes were also found to contain a variety of aerobic and anaerobic bacterial. In 10 of 26 patients with acute salpingitis (37.5 per cent), aerobic and/or anaerobic bacteria were isolated from the fallopian tubes.

The involvement of a mixed aerobic-anaerobic bacterial flora in salpingitis is similar to the pattern seen in patients with other types of pelvic infections.[23, 29, 30] In an experimental animal model, Weinstein and associates[31, 32] described a biphasic disease process for intra-abdominal infection. The initial phase was peritonitis and sepsis in which the major organisms involved were gram-negative faculatative aerobes, especially *E. coli*.

The second stage was intra-abdominal abscess formation in which the identified organisms were anaerobic bacteria. Their data suggested that to prevent both the peritonitis and abscess stages an antibiotic treatment regimen that covered the gram-negative aerobic and anaerobic bacteria was necessary. Whether this treatment approach is necessary in clinical situations is uncertain.

To achieve the preservation of fertility and to prevent the sequelae of acute salpingitis such as pyosalpinx, hydrosalpinx, tuboovarian abscess, dyspareunia, pelvic adhesions, and chronic pelvic pain, treatment regimens should be instituted that are based on a knowledge of the microorganisms involved in acute salpingitis. The initial step is to obtain specimens for microbiologic evaluation directly from the source of infection—the fallopian tubes. Then prospective, microbiologically controlled treatment regimens must be evaluated for short-term and long-term prognosis in patients with acute salpingitis. Many of the regimens currently used are based on the assumption that the gonococcus is the major etiologic agent in acute salpingitis. We believe that *N. gonorrhoeae* is an important

but not the only significant causative agent in the pathogenesis of acute salpingitis. Our study has confirmed the presence of a variety of microorganisms in the fallopian tube of patients with acute salpingitis. More commonly then the gonococcus, mixed aerobic-anaerobic bacteria have been isolated from the peritoneal fluid and/or fallopian tube exudate in patients with acute salpingitis. Rarely, genital tract mycoplasma have been identified in the fallopian tube or culdocentesis aspirates. It has been suggested that *C. trachomatis* is a major etiologic agent in acute salpingitis. We have not been able to confirm this finding, but further investigations are necessary to evaluate the possible role of *C. trachomatis* in the pathogenesis of acute salpingitis.

This study demonstrates that identification of gonococci in the endocervices of salpingitis patients does not prove that *N. gonorrhoeae* is present in upper genital tract disease. Utilization of Fallopian tube and peritoneal cultures has demonstrated that, in addition to the gonococcus, there is an involvement of a mixed aerobic-anaerobic flora in salpingitis patients that is similar to that seen in other female genital tract infections. In addition, mycoplasma infrequently may be present.

It has been suggested that the gonococcus may only be of importance to initiate the infection and to pave the way for other pathogenic bacteria from the cervical and vaginal flora to gain access to the upper genital tract.[9] Monif and colleagues[10] have postulated that there is an anaerobic superinfection with nonrecovery and probably elimination of *N. gonorrhoeae*. Lip and Burgoyne[27] noted that the isolation of *N. gonorrhoeae* was dependent on the stage of infection. They recovered the gonococcus from the cul-de-sac frequently within two days of the onset of salpingitis but infrequently if symptoms had been present greater than seven days. Their data support the idea of progression from gonococcal to mixed aerobic-anaerobic infection.

On the other hand, the failure to isolate *N. gonorrhoeae* in purulent exudate from the Fallopian tube or peritoneal fluid may be due to the ability of the gonococcus to attach to epithelial cells. Studdiford and colleagues[33] and Tronca and co-workers[34] were able to isolate *N. gonorrhoeae* from tissue but not the purulent exudate.

Our initial data suggest that caution be used in evaluating the use of culdocentesis to obtain culture material. Further studies must be done to either prove or disprove that culdocentesis aspirates reflect the microorganism mileau present in the Fallopian tubes of patients with acute salpingitis. Finally, long-term follow-up studies based on microbiologically controlled antibiotic treatment are necessary. We need to discover if a particular pathogen(s) carries(y) a worse prognosis for future fertility.

Whether treatment must provide coverage against *N. gonorrhoeae*, mixed aerobic-anaerobic bacteria, mycoplasma, and *C. trachomatis* is not clear at the present time. What appears clear is that eradication of the gonococcus may not be adequate treatment for patients with acute salpingitis. At the present time, we believe that doctors administering antibiotic treatment for patients with acute salpingitis should be cognizant of the polymicrobial nature of this infection.

Psychological aspects of chronic pelvic pain in women

M. RENAER, M.D., PH.D., F.R.C.O.G. (a.e.)

T. VAN HEMELRIJCK, M.A.
Leuven, Belgium

Three psychometric tests: (1) A Dutch adjustment of the Minnesota Multiphasic Personality Inventory (MMPI), (2) The Amsterdam Biographical Questionnaire (ABV-V), and (3) The Interpersonal Relations Questionnaire (VIR) were administered to three groups of patients: (1) fifteen patients with chronic pelvic pain without clear organic cause; (2) twenty-two patients with chronic pelvic pain due to endometriosis; and (3) twenty-three pain-free patients. The analysis of the results showed that Groups 1 and 2 did not differ significantly on the MMPI and a global view of the two pain groups indicates a neurotic behavior, but both Groups 1 and 2 differed from Group 3 (the control group) and from Group 4 (the standardization group of the adapted MMPI). On the ABV-V the pain groups' answers were similar to those of neurotic patients, while the patient control group showed a certain neurotic tendency. The results on the VIR lead to the conclusion that Group 2 has the same profile as Group 1, although they did not deviate as strongly from the control group. As it is improbable that chronic pain for which an organic cause has been found occurs predominantly in patients with neurotic personality structure or neurotic reactions, we must admit that chronic pain with an organic origin can lead to neurotic reactions. These data confirm earlier studies on neurologic patients and on patients with chronic low back pain. Because even the patient control group showed a certain neurotic tendency, it follows that every contact with the medical world results in some degree of uncertainty and that the selection of control groups, when psychosomatic problems are being studied, is especially difficult. (AM. J. OBSTET. GYNECOL. 134:75, 1979.)

AMONG WOMEN who complain of chronic gynecologic pain are a significant percentage in whom the complaints have no clear organic basis. This problem is well known in gynecologic practice; in the gynecologic literature it has been called by many diverse names, and Naujoks, years ago, was already speaking of "die Krankheit mit den zwanzig Nahmen," the disease with 20 different names. Under these circumstances it seems logical to attempt to ascertain whether psychogenic factors contribute to either the origin or the maintenance of this condition.

In two recent studies concerning patients with chronic pelvic pain,[1, 2] the presence or absence of organic lesions of the internal genitals was ascertained and subsequent psychometric parameters were used to make a psychological evaluation of the patients. These parameters were also used to evaluate a control group of patients without pain. Castelnuovo and Krout[1] found a clear heightening of the hypochondriasis (HS), depression (D), and hysteria (Hy) scales of the MMPI for the patients with chronic pain. However, they also found heightened scores for the control patients. However, this study is not very informative concerning chronic pain without clear pathology, because patients with this sort of pain were not separated from those with pain of organic origin. It is also regrettable that no tests were carried out to see if there were significant differences between the groups with or without pain on the several distinct variables.

Beard and associates,[2] on the other hand, divided the patients into groups with or without probable organic cause for their pain and also included a control group. Neither the nature of the control group nor the duration of the complaint of pain was disclosed. With the

Eysenck Personality Inventory (EPI) a significant difference was found on the neuroticism (N) score between the control group and the pain group without probable organic cause. The mean N score for patients with pain and organic pathology fell between that of the laparoscopy-negative patients with pain and the control group, differing with neither significantly. The extraversion (E) scores did not show significant differences between groups. With the Middlesex Hospital Questionnaire, which tapped principally neurotic symptoms and syndromes, Beard and colleagues[2] found no significant differences among their three groups.

Woodforde and Merskey,[3] by using the Middlesex Hospital Questionnaire and the Eyseck Personality Inventory, studied a group of patients with chronic pain of a physical (neurologic) origin in comparison with a group of patients in whom the chronic pain seemed to have a psychogenic origin. Sternbach and associates,[4] using the MMPI, compared patients complaining of chronic low-back pain with objective disorders with patients complaining of chronic low-back pain without clear organic disorders. Both of these authors reported no significant differences between these two experimental groups, which agrees with our findings.

Patient groups and methods

Renaer,[5] after a careful examination of 108 patients with chronic pelvic pain, diagnosed 28 of these cases as "chronic pain without obvious pathology." In 24 of those 28 cases a psychopathologic examination was conducted, unearthing in the course of one or more interviews, definite psychopathologic factors in 20 of them. It is difficult, however, to conduct these psychopathologic examinations in control cases; and even if this were done the results would not enable one to make statistical comparisons. Therefore a battery of psychometric tests was administered. These have the advantage of offering standardized results to which all subjects can be compared. At the same time the results of the psychological tests are amenable to statistical procedures and can be used to test certain hypotheses. Thus, psychometric tests were administered to three groups of patients: Group 1—fifteen patients with chronic pelvic pain without clear organic cause; Group 2—twenty-two patients with chronic pelvic pain and endometriosis, the chronic pain being most probably due to the endometriosis; and Group 3—twenty-three control patients.

The 15 patients with chronic pelvic pain without clear organic cause were patients who had for several months complained of pain. Most of them had been seen repeatedly at the gynecologic outpatient clinic, and all were subjected to a thorough examination, always including a laparoscopy, so that nongynecologic sources of pain could, with a high probability, be eliminated. In the 22 patients with chronic pelvic pain probably caused by endometriosis the presence of endometriosis lesions had been verified by laparoscopy, and the presumption that the pain was a consequence of the endometriosis lesions seems highly reasonable.

The 23 control subjects were patients who were admitted into the gynecologic clinic for benign nonpainful conditions that were not due to any psychogenic factors, e.g., patients with a benign tumor of the ovary found during a routine examination, a number of patients who underwent a curettage for intermenstrual bloodloss occurring either spontaneously or under ovulation inhibitors, or patients with a slight degree of bladder descent without urinary incontinence. In the selection of the control subjects, we attempted to find patients of about the same age, civil status, and educational level as the first two groups.

The psychological functioning of these three groups of patients was evaluated by the following psychological tests.

The Minnesota Multiphasic Personality Inventory. The Dutch adjustment by Nuttin and Beuten[6] of the MMPI of Hathaway and Kinley[7] was used. This gives the following list of clinical variables: HS = hypochondriasis, D = depression, Hy = hysteria, Pd = psychopathic deviation, Mf = masculinity/femininity, Pa = paranoia, Pt = psychasthenia, Sc = schizophrenia, Ma = hypomania, Si = social introversion. As validity scales to check the honesty of the answers the following were included: L = lie, F = validity, K = correction. At the end of the test were added: Es = ego-strength scale, R = repression scale, A = anxiety scale.[8, 9]

The Amsterdam Biographical Questionnaire. The ABV-V of Wilde[10] with four scales was also used: N = neurotic instability as manifested by the presence of psychoneurotic complaints, NS = neurotic instability as manifested by the presence of functional somatic complaints, E = social extraversion, and T = test-taking attitude.

Interpersonal Relations Questionnaire. The VIR questionnaire of Vertommen and Rochette[11] examines the male-female relationship. Our research concerned only the woman's view of her marriage. On both the reality and desired levels we examined how the wife felt about her husband (I → husband) and what the wife supposed that the husband felt about her (my husband → me). Eight content variables were measured: L = dominance, K = sociability, R = nurturance (tendency to offer help, support, and sympathy), B = dependence, S = abasement (a proneness to take blame, belittle oneself, and to apologize), Ve = detachment

(aloof, withdrawn, and seclusive behavior), Vij = hostility, and A = autonomy.

The purpose of these various tests was to explore the psychological background of the three groups of patients and at the same time to make a quantitative addition to the above-mentioned psychopathologic evaluations.

The following hypotheses were tested: (1) The scores on the tested variables by women with chronic pelvic pain without a clear organic cause (Group 1) are significantly different from the scores of women whose chronic pain is most likely of organic origin (endometriosis, Group 2). (2) The scores of the women with chronic pelvic pain without clear organic origin (Group 1) differ significantly from those of the control group of women without pain complaints (Group 3). (3) The scores of the women with chronic pelvic pain of organic origin (endometriosis, Group 2) are significantly different from the control group of women with no pain complaints (Group 3).

A multivariate variance analysis was used to evaluate our findings, namely, the MANOVA computer program of Cooley and Lohnes.[12] This analysis compares the dispersions and centroids of the different groups. By rejecting the null hypothesis concerning the centroid equality one can, by means of the univariate F values, determine which of the test variables best differentiates between the various groups. Where appropriate, Student's t test was done for significance of difference.

When the results from the various groups were known, a comparison between the means of the standardization group of the test was also done. That standardization group is Group 4. For the comparisons which refer to Group 4 no multivariate test could be performed, as we do not possess the required detailed information. We thus tested the means by the Fischer's t test for uncorrelated means.[13]

Results

The composition of the three groups regarding age, civil status, number of children, and the level of education is shown in Table I. The results for each psychological test will be discussed separately.

MMPI. In Table II we give the means and standard deviations in t scores for the various groups. For Group 4 the mean is 50 with a standard deviation of 10. Fig. 1 gives the graphic representation of the results, whereas the analysis of variance and t test are presented in Table III.

Multivariate variance analysis and t test on the results show that Groups 1 and 2 do not differ significantly on the clinical scales of the MMPI, while both Groups 1 and 2 do differ from Group 3 as well as from Group 4 (the standardization group). The two control groups (3 and 4) also appear to differ from each other.

Fig. 1 clearly shows similar profiles for Groups 1 and 2, the two pain groups. The inflated scores on hypochondriasis, depression, and hysteria clearly contrast with the two control groups, while the former groups (1 and 2) also display, when compared with Group 3, higher scores on psychasthenia (Pt), social inversion (Si), and anxiety (A), as well as lower scores on ego strength (Es).

A global view of the two pain groups (1 and 2) plainly indicates a neurotic behavior. The difference between

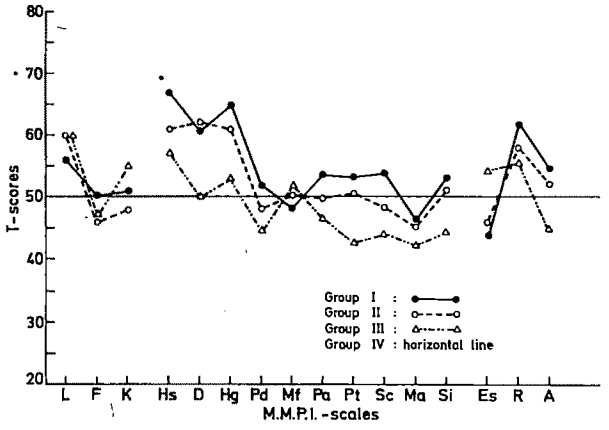

Fig. 1. Graphic presentation of the means of the different groups on the MMPI scales in t values. Abbreviations: *L* = lie, *F* = validity, *K* = correction, *Hs* = hypochondriasis, *D* = depression, *Hy*= hysteria, *Pd* = psychopathic deviation, *Mf* = masculinity/femininity, *Pa* = paranoia, *Pt*= psychastenia, *Sc* = schizophrenia, *Ma* = hypomania, *Si* = social introversion, *Es*=ego-strength scale, *R* = repression scale, *A* = anxiety scale.

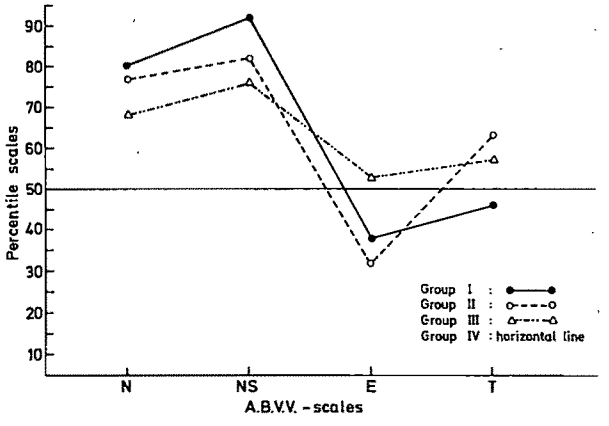

Fig. 2. Graphic presentation of the results of Table IV in percentile form. Abbreviations used: *N* = neurotic instability as manifested by the presence of psychoneurotic complaints, *NS* = neurotic instability as manifested by the presence of functional somatic complaints, *E* = social extraversion, *T* = test-taking attitude.

the two control groups lies principally in higher scores for the patient control group on hypochondriasis (Hs), psychopathic deviation (Pd), repression (R), and a lower score on anxiety (A) and on the scales that rather denote tendencies toward psychotic behavior.

ABV-V. In Table IV are given the means and standard deviations in raw scores and percentiles for the various groups; these results are expressed in percentile form in Fig. 2. As stated above, the comparison cannot include Group IV as the necessary data are not available.

From multivariate variance analysis on ABV-V for the different groups it appears that the two pain Groups 1 and 2 do not differ from each other on the ABV-V scales, and they do not differ from the patient control group. At an univariate level there is a significant difference between Group 1 and Group 3 on the NS scale. Patients with pelvic pain without clear organic cause display a stronger neurotic tendency manifested by functional somatic complaints, than the patient control group. (F = 6.73; this is significant at the 5% level).*

Fig. 2 clearly shows that the profiles from the two pain groups are very nearly parallel, although there is a tendency for Group 1 to be more neurotic and less defensive than Group 2. However, this difference is not a significant one. At the same time Fig. 2 shows that the patient control group differs from the norm group by a heightened neurotic tendency (N and NS). We were, however, not able to test this difference for significance.

Thus the results presented in this section are in the same direction as those of the MMPI, in that the two pain groups did not differ from each other significantly, while there is a difference between the two pain groups and the norm group. On the other hand in this test, a difference between the patient control group and the norm group is also indicated. Thus we can conclude that also on the ABV-V the pain groups answer as do neurotic patients, while the patient control group shows a certain neurotic tendency.

VIR. Space does not allow us to reproduce the means and standard deviation or the multivariate variance analysis and t test on the VIR for the different groups.† They show that Group 1 (pain without clear pathology) differs from Group 3 (patient control group) and Group 4 (norm group) concerning interpersonal functioning in marriage. The patients from Group 1 describe themselves as very unfriendly toward their husbands. On the other hand they wish very strongly that the marriage relationship would be characterized by the absence of detachment and suspicion. This interpersonal picture of the relationship indicates marriage conflicts which block positive emotional feelings toward the husband. On the other hand it appears from their wishes that they cannot tolerate any negative elements in their relationship, whether from their own side or especially from that of the husband.

Group 2 (pain and organic pathology) does not deviate significantly from Group 3 (patient control group) or from Group 1 concerning interpersonal functioning. Inspection of the results leads to the conclusion that to some degree Group 2 has the same profile as

*The results of the multivariate variance analysis will be sent on request.

†These data will be sent on request.

Group 1, although this group did not deviate so strongly from the control group.

One difference between the two pain groups can be seen if we compare them with the control group. Where the patients in Group 1 emphasized in their wishes that no negative feelings could be tolerated, Group 2 emphasized more the wish for greater dependence on each other within the relationship. In general we could remark that while Group 1 is fixated primarily on negative aspects that are to be avoided at any cost, Group 2 envisions a more positive relationship where each person can receive help and support from the other.

Comment

One may wonder why Group 1, the experimental group, comprised only 15 patients, whereas there were 22 in Group 2 and 23 in the patient control group. In fact it was our intention to administer the various tests to 28 patients with chronic pelvic pain without clear organic cause. Whereas the patients of groups 2 and 3 were very cooperative, several patients among the 28 of Group 1 were not, and only 15 completed the questionnaires. This leaves us with the interesting question of precisely why patients of this group showed this resistance to the psychological examination. It is possible that the patients who did not comply with our request had more psychological problems than those who completed the questionnaires.

Greater numbers, especially in Group 1 might have allowed us to find differences between more variables in the various groups than those uncovered by the statistical analysis, but this does not detract from the value of the present results. From these results it appears that our first hypothesis: "There is a significant difference between the variables concerning psychic functioning (as measured by our instruments) of patients with chronic pain but no clear organic cause and

those with chronic pain with an organic cause," must be rejected.

At this time it is difficult to accept the idea that chronic pain for which an organic cause has been found occurs predominantly in patients with neurotic personality structures or neurotic reactions. Therefore we must suppose the converse, that chronic pain with an organic origin can lead to neurotic reactions. This is indeed verified indirectly by the results of Sternbach and associates.[4] Using the MMPI, they compared patients with lower back pain of less than six months (acute) with patients whose lower back pain had endured more than six months (chronic). They found that the patients with acute lower back pain exhibited clearly milder neurotic symptoms than those with chronic back pain.

The question occurs also whether pain is more likely to become chronic in patients with previously existing neurotic personality structures. Research on this hypothesis would require further studies in which the personality structure before the onset of pain could in some way be measured. Surprisingly, when we examine the scores of our patient control group, we see that this group differs on several variables from the group on which the criteria were standardized.

Apparently Group 3 should be considered as a control group in a restrictive sense, i.e., in so far as these patients did not complain of pain; to obtain a truly good control group one must go outside the patient population. For this reason the scores of the three groups of our study were compared with the scores of the standardization group of the MMPI adapted by Nuttin and Beuten,[6] the ABV-B, and the VIR.

The comparison between Groups 1 and 4 shows more clearly that Group 1 exhibits a neurotic symptomatology, with heightened scores on hypochondriasis, depression, hysteria, and repression, and lower scores on ego strength (MMPI) and with heightened scores on neurotic instability (ABV-V).

Analogous results are found when Group 2 is compared with Group 4. The comparison between our patient control group (Group 3 and Group 4 is very interesting; we find in the patient control group a tendency toward high scores on hypochondriasis and on psychopathic deviation but, more strikingly, clearly lower scores on tests that indicate psychotic deviations: psychasthenia (Pt), schizophrenia (SC), hypomania (Ma), social introversion (Si); on the other hand there was an increase on repression (MMPI). On the VIR the patient control group presents a very idealistic view about their relationship with their husband. In the selection of the control group we felt that acceptable controls would be patients who were admitted to the clinic for symptoms or diseases that were not accompanied by pain, apparently had no psychogenic components, and were considered benign by the selecting gynecologist. Examples of these would be patients with slight blood loss between menstruations, either spontaneously or after taking the "pill," and patients with an incidentally discovered ovarian cyst or with descent of the bladder without urinary incontinence. The above-mentioned deviations of Group 3 from the norm Group 4 seem to indicate that the exposure to a clinical situation, even for symptoms whose nonmalignity is stressed by the doctor, but which nonetheless call for a surgical operation, promotes a person to "patient" status with the attending fear, uncertainty, and denial (MMPI). This may lead the patient to present an exaggeratedly idealistic image of herself (VIR). If we accept the idea that every contact with the medical world results in some degree of uncertainty, it follows that the selection of control groups when studying psychosomatic problems is especially delicate.

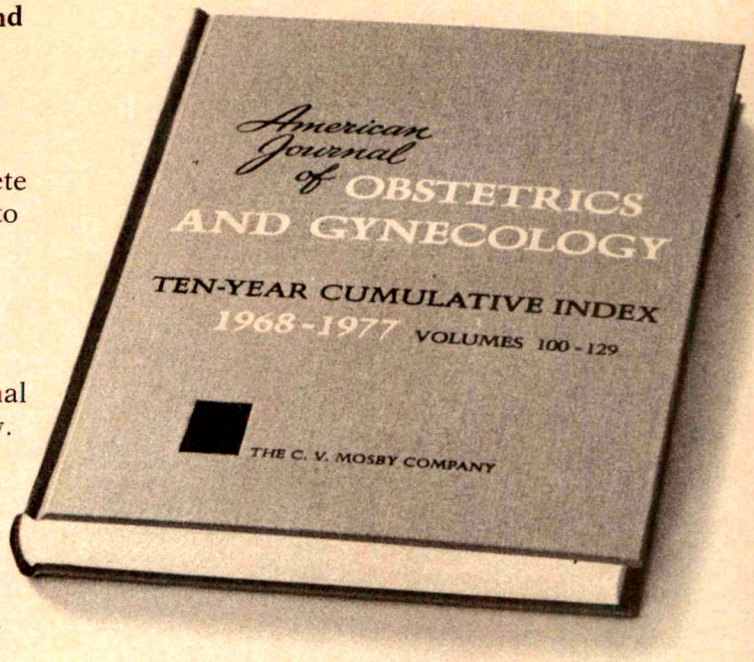
La pratique des accouchemens soutenue d'un grand nombre d'observations . . .

PAUL PORTAL
Paris, Gabriel Martin, 1685



One of the major obstetric works of the late seventeenth century was that of Portal. A student of François Mauriceau and later a successor to him, and director of the obstetric service of the Hôtel Dieu, Portal based his treatise on clinical observations collected for more than 30 years. His 81 case reports possess a rare charm in their simplicity and clearness and reveal Portal's unique talents of observation. In the prefatory remarks he noted, "As I am ready to confess that my genius tends not in any wise to writing, so I hope the courteous reader will excuse the errors he may perhaps meet with in the following treatise, expecially since being sufficiently sensible, as well of my inability as the little inclination I had to publish these observations, the same would have laid concealed within the compass of my closet, had not some of my friends . . . persuaded and most urgently pressed me to oblige the world with what they were assured would tend to the instruction of those that profess midwifery . . .. I must intreat the reader, to have a regard not so much to the style and nicety of choice words . . . as the weight and truth of the matter itself . . .." Portal's chief contribution to the science of obstetrics lay in his clear recognition of placenta previa and its anatomy and clinical importance. Although previous writers, including those of the Hippocratic school and Ambroise Paré and Mauriceau, mentioned "flooding" preceding the delivery of the child (in fact, it was for this serious complication that Paré reintroduced podalic version), none of these authors recognized the true nature of this entity. In contrast, Portal not only reported eight cases in some detail (and alluded to six more) but also in these reports recognized that the placenta was attached over the lower uterine segment at or near the internal os. In addition, he detailed version and breech extraction and described how the placenta separates from the uterus. A typical "observation" (No. 69) was that of a patient who had bled for several days. On examination, Portal found the cervix well dilated. "I could put in three of my fingers foremost; I search'd with one finger first and found the afterbirth foremost, and closely joined around the inner orifice of the womb, which was the occasion of the excessive flux of blood; and as it had reduced the woman to a very low condition, so this joined to the other circumstances, made me fear the life both of the woman and child." After sending for a physician who prepared a prescription for the patient, Portal noted that the hemorrhage continued and he resolved to deliver her. He wrote: ". . . notwithstanding the great danger that must needs attend it . . . I found some means to convey my hand (well greased before)

0002-9378/79/090081+02$00.20/0 © 1979 The C. V. Mosby Co.

into the inner orifice of the womb, where I again felt the afterbirth fasten'd to it . . . I peel'd it off by degrees, and brought it out; and then turning my hand again in the womb, the first thing I met with, was the navel-string, along which I guided my hand first to the child's belly, and then downwards to the thigh, and thence lower to the leg and foot which I brought out and baptized . . .. Whilst I was pulling this foot the other followed, and the whole body after it." Portal noted that the child was alive and that the woman, who had been practically moribund, shortly recovered consciousness. Subsequently, the patient had a slow convalescence with an intermittent fever. In another case (No. 51), he explained the source of the bleeding and the circumstance of its production. He observed: "(I) found the afterbirth placed just before and quite across the whole inner orifice, which had actually been the occasion of the flux of blood: for, by the opening of the orifice, the said afterbirth then being loosened from that part where it adhered to before, and the vessels containing the blood torn and opened, produced this flooding, which sometimes is so excessive, as proves fatal to the woman, unless it be speedily prevented." It was not until a number of years later that P. Gottlieb Schacher demonstrated at autopsy that placenta previa was implanted over the lower uterine segment (De placentae uterinae morbis, Leipzig, 1709) and Edward Rigby first differentiated between placenta previa (unavoidable hemorrhage) and abruptio placentae (accidental hemorrhage) (Essay on Uterine Haemorrhage, London, 1775). Portal's treatise included his demonstration that podalic version could be performed with one foot, a procedure which, with Mauriceau and Jacques Guillemeau, he helped popularize after Paré. He also taught that face presentation usually ran a normal course and should be treated expectantly. In contrast to many of his contemporaries who practiced *accouchment forcé*, Portal advocated that dilatation of the cervix be left to nature. Although hydatidiform mole had been described previously, Portal published the first illustration of this condition (see figure) and the first detailed account of its removal by digital intrauterine manipulation (Observation No. 40). Portal wrote: ". . . I brought my finger (well greased with oil of sweet almonds) into the neck of the womb, and found the inner orifice much inflammed . . .. Advancing with my finger further into the womb, I felt a soft substance closely adhering to the inward orifice, which I supposing to be the afterbirth, I separated the adjoining parts from the orifice, without bruising it, when part of this soft spongy substance breaking off from the rest, I brought out a piece of the bigness of a walnut . . .. And the pains continuing, I pulled out a great part of this strange substance, which appeared full of fibers and white bladders full of water, glistering like crystal, and in shape not unlike our white currants. The quantity I brought forth weighed about two pounds . . .. Whilst my right hand was within the womb, I put the left to the woman's belly to push the womb downwards, which was of the bulk of a loaf of two or three pounds. The . . . figure [see illustration] represents a false conception, resembling in shape a bunch of currants, and in substance the seed of frogs." An English translation of Portal's treatise appeared in 1705 (The Compleat Practice of men and women midwives, or the true manner of assisting a woman in childbearing: illustrated with a considerable number of observations, London, H. Clark and J. Taylor).

New! Available for the first time

The ten-year **cumulative author and subject index** to volumes 100-129 (1968-1977) of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY is now available for your journal collection. It is a complete and comprehensive reference guide to over 28,000 pages of authoritative articles published in the Journal during the past ten years.

The world-renowned "Gray Journal" is the oldest specialty journal devoted to obstetrics and gynecology.

Now these influential papers, appearing between 1968-1977, have been cross-referenced to include over 23,100 subject entries. Each entry lists the complete article title, author(s), volume, page, and year of publication.

The author index lists more than 13,850 contributors from this period, along with respective article title, author-to-author referral, volume, page, and publication date.

The 479-page index is handsomely presented in a rust and gold cloth-cover volume. It is a must for every library concerned with obstetrics and gynecology. Send for your copy of this valuable reference today!

479 pages, 8¼" × 11", price $28.75

Preg/Stat™.
Now, first in first week detection.
With just a 30 minute incubation.

Sensitivity of 15 mIU/ml and outstanding performance in qualitative and semi-quantitative early pregnancy testing.

Introducing Serono's new Preg/Stat Beta-hCG RIA Kit.

It's the earliest, fastest, simplest and most accurate RIA early pregnancy test available. With sensitivity that's unmatched in both qualitative "yes/no" and semi-quantitative procedures.

Sensitivity that's crucial for earlier-than-ever results.

And after all, an early answer is what it's all about in pregnancy testing.

You can't take a chance with a test less sensitive.

In ectopic pregnancy. Preg/Stat measures much smaller amounts of hCG than Biocept-G or conventional tube and slide tests.

Prior to certain X-rays, drug therapy or surgery. It's imperative that every pregnancy be ruled out in its earliest stages.

Before menstrual extraction. Many times, menstrual extraction procedures are performed on patients who are not actually pregnant. Our unsurpassed accuracy allows Preg/Stat to successfully confirm each pregnancy before termination.

Problem pregnancies. Preg/Stat allows monitoring to begin within the first week.

Infertility treatment. With pregnancy confirmed within the first week, infertility medications can be discontinued as soon as possible to avoid any potential problems.

When the patient needs to know. In cases where termination is advisable for medical reasons, today's woman doesn't want to wait weeks to find out if she's pregnant.

In addition, with the growing concern over the child's well-being from the very beginning, she may want to protect the child from any of her activities that may be harmful.

All these performance features with just a 30 minute incubation.

Sensitivity down to 15 mIU/ml. Preg/Stat measures hCG down to 15 mIU/ml, compared to Biocept-G (RRA) at 200 mIU/ml. No other early pregnancy test comes close to this exceptional sensitivity.

Less sensitive results may mean more false negatives and more retesting in borderline cases.*

Qualitative and semi-quantitative results. As a qualitative "yes/no" test, Preg/Stat offers sensitivity down to 15 mIU/ml.

As a semi-quantitative test, Preg/Stat allows you to approximate both the quantity of hCG and the week of pregnancy.

Approximately 1.0% cross-reactivity with LH. Our cross-reactivity with LH is approximately 1.0%. Other tests, including Biocept-G, have a higher degree of cross-reactivity.

Accuracy of 100%. Several recovery tests were performed in normal male serum, beef serum and EDTA plasma. After adding known amounts of hCG, the mean percent of hCG recovered approximated 100%.

Speed and simplicity. Preg/Stat offers the advantages of RIA sensitivity without the lengthy incubation times associated with other RIA tests.

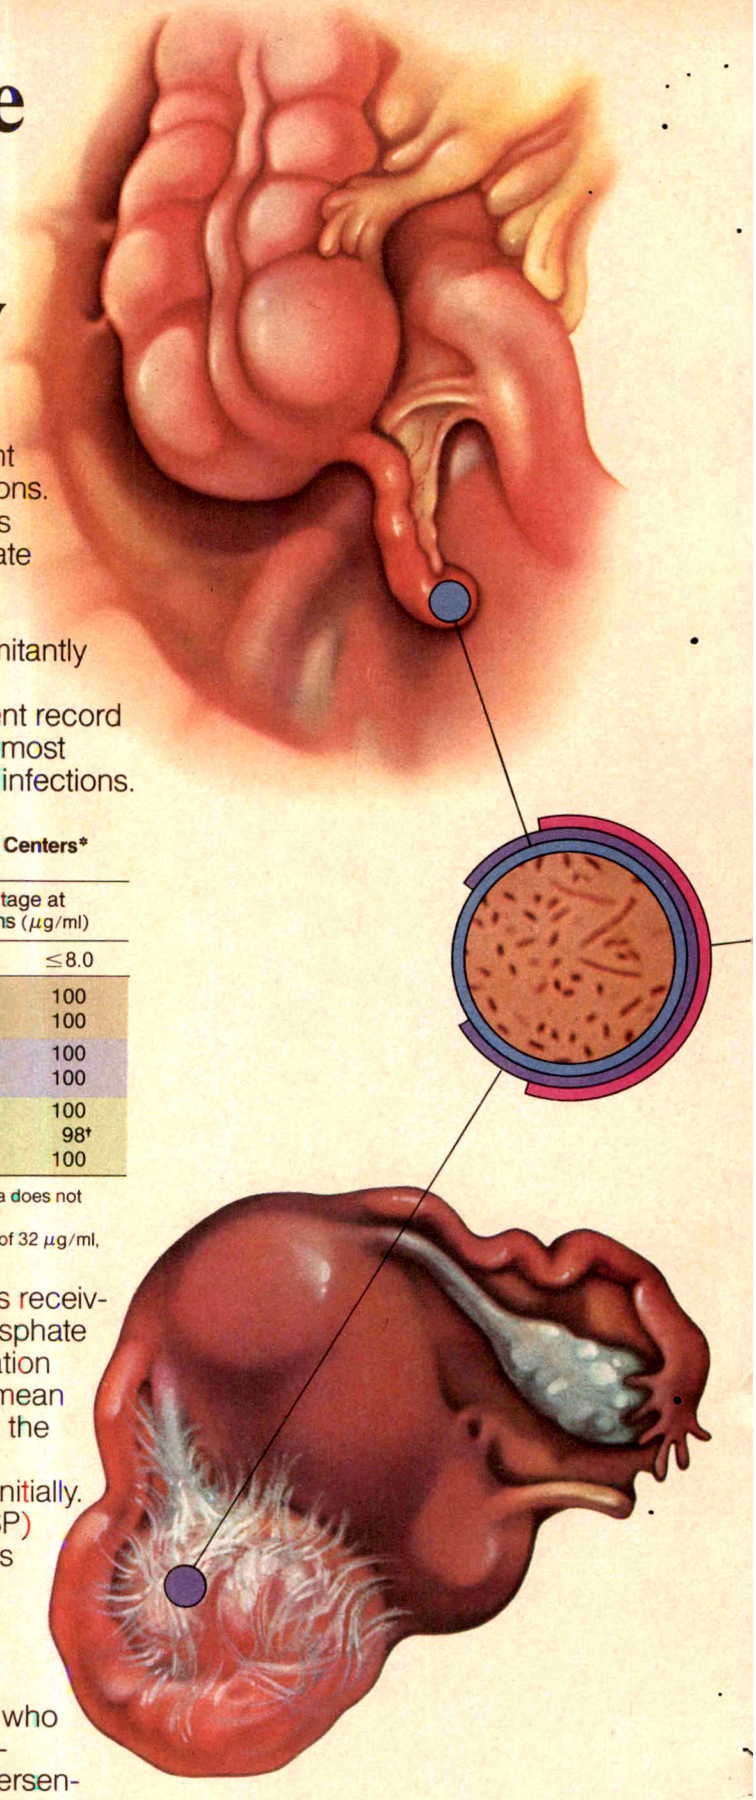
Find out more. Just contact your Serono representative.

"I can't wait. I have to know if I'm pregnant."

*In an independent research laboratory setting, 90 samples were evaluated using Preg/Stat and Biocept-G (Wampole Laboratories, Cranberry, N.J.). All negatives were reassayed using a quantitative hCG-β subunit radioimmunoassay in order to rule out false negatives.

Of the 90 samples surveyed, there were 65 negatives by Preg/Stat, of which 63 were less than 5 mIU/ml as confirmed by the quantitative hCG-β assay. The two remaining samples were 9.0 and 9.6 mIU/ml respectively.

There were 25 positive results by Preg/Stat and quantitative hCG-β subunit RIA. However, only 22 of these results were confirmed positive by Biocept-G. The 3 samples ruled negative by Biocept-G and positive by the other two above-mentioned methodologies had values of 65.2, 181.4 and 65.7 mIU/ml hCG.



In this comparison, neither Preg/Stat nor Biocept-G produced false results within the respective methodology.

However, these results demonstrate that Preg/Stat is capable of detecting pregnancy earlier than Biocept-G.

Five years of clinical experience for the serious anaerobic infection you treat today

Extensive research and clinical experience have established that anaerobic bacteria, once thought innocuous, are often the cause of serious infections.

During this time, clinical experience has also established the efficacy of Cleocin® Phosphate (clindamycin phosphate injection, NF) in serious anaerobic infections—primarily intra-abdominal sepsis and female pelvic infection—used concomitantly with appropriate surgical procedures.

Clindamycin has maintained an excellent record of in vitro activity against *Bacteroides fragilis,* the most commonly isolated anaerobic pathogen in these infections.

In Vitro Susceptibility of *B. fragilis* at Three Infectious Disease Centers* as Determined by Agar or Broth Dilution Method

Center	Years	Number of Strains Tested	Cumulative Percentage at Various Concentrations (μg/ml)		
			≤2.0	≤4.0	≤8.0
Mayo	to 1972	195	96	100	100
	1974-76	92	93	100	100
Wadsworth	to 1972	123	89	96	100
	1972-75	76	84	96	100
Tufts	1973-76	26	100	100	100
	1977	59	98	98	98†
	1978	37	100	100	100

*Published data or data on file with The Upjohn Company. The use of this data does not constitute, imply, or suggest a recommendation of Cleocin by these centers.

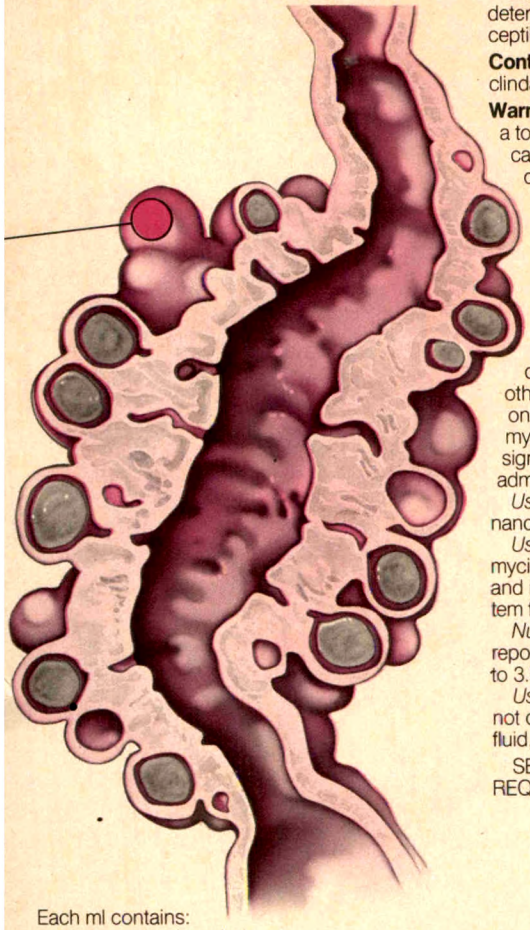
†Of 678 strains tested at these centers, only one resistant strain, with an MIC of 32 μg/ml, was encountered.

In a study of six healthy male volunteers receiving 600 mg intravenous infusions of Cleocin Phosphate every six hours, the mean peak serum concentration following the fourth dose was 10.42 μg/ml. The mean serum concentration immediately before infusing the fourth dose was 3.27 μg/ml.

The parenteral route is recommended initially. Oral Cleocin® HCl (clindamycin HCl capsules, USP) may be instituted when the patient's clinical status has improved.

As there is no cross-allergenicity to the β-lactam antibiotics, such as the penicillins and cephalosporins, Cleocin is useful in seriously ill patients infected with susceptible organisms and who are sensitive to drugs in those classes. Hypersensitivity to clindamycin has been reported; if a hypersensitivity reaction occurs, the drug should be discontinued.

© 1979 THE UPJOHN COMPANY



WARNING

Clindamycin therapy has been associated with severe colitis which may end fatally. Therefore, it should be reserved for serious infections where less-toxic antimicrobial agents are inappropriate, as described in the INDICATIONS section. It should not be used in patients with nonbacterial infections, such as most upper respiratory tract infections. Studies indicate a toxin(s) produced by *Clostridia* is one primary cause of antibiotic-associated colitis. See WARNINGS section. The colitis is usually characterized by severe, persistent diarrhea and severe abdominal cramps and may be associated with the passage of blood and mucus. Endoscopic examination may reveal pseudomembranous colitis.

When significant diarrhea occurs, the drug should be discontinued or, if necessary, continued only with close observation of the patient. Large-bowel endoscopy has been recommended.

Antiperistaltic agents such as opiates and diphenoxylate with atropine (Lomotil®) may prolong and/or worsen the condition.

Diarrhea, colitis, and pseudomembranous colitis have been observed to begin up to several weeks following cessation of therapy with clindamycin.

Each ml contains:
clindamycin phosphate equivalent to ..... 150 mg clindamycin
benzyl alcohol ..... 5 mg
disodium edetate ..... 0.5 mg
water for injection ..... qs
When necessary, pH adjusted with NaOH and/or HCl.

Indications: Clindamycin is indicated in the treatment of serious infections caused by susceptible anaerobic bacteria.

Clindamycin is also indicated in the treatment of serious infections due to susceptible strains of streptococci, pneumococci, and staphylococci. Its use should be reserved for penicillin-allergic patients or other patients for whom, in the judgment of the physician, a penicillin is inappropriate. Because of the risk of colitis, as described in the WARNING box, before selecting clindamycin the physician should consider the nature of the infection and the suitability of less-toxic alternatives (eg, erythromycin).

Anaerobes: Serious respiratory tract infections such as empyema, anaerobic pneumonitis and lung abscess; serious skin and soft-tissue infections; septicemia; intra-abdominal infections such as peritonitis and intra-abdominal abscess (typically resulting from anaerobic organisms resident in the normal gastrointestinal tract); infections of the female pelvis and genital tract such as endometritis, nongonococcal tubo-ovarian abscess, pelvic cellulitis and postsurgical vaginal-cuff infection.

Streptococci: Serious respiratory tract infections; serious skin and soft-tissue infections; septicemia.

Staphylococci: Serious respiratory tract infections; serious skin and soft-tissue infections; septicemia; acute hematogenous osteomyelitis.

Pneumococci: Serious respiratory tract infections.

Adjunctive Therapy: In the surgical treatment of chronic bone and joint infections due to susceptible organisms. Indicated surgical procedures should be performed in conjunction with antibiotic therapy.

Bacteriologic studies should be performed to determine the causative organisms and their susceptibility to clindamycin.

Contraindications: History of hypersensitivity to clindamycin or lincomycin.

Warnings: See WARNING box. Studies indicate a toxin(s) produced by *Clostridia* is one primary cause of antibiotic-associated colitis. Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed promptly with fluid, electrolyte, and protein supplementation as indicated. Systemic corticoids and corticoid retention enemas may help relieve the colitis. Other causes of colitis should also be considered.

A careful inquiry should be made concerning previous sensitivities to drugs and other allergens. Antagonism has been demonstrated between clindamycin and erythromycin in vitro. Because of possible clinical significance, these two drugs should not be administered concurrently.

Usage in Pregnancy: Safety for use in pregnancy has not been established.

Usage in Newborns and Infants: When clindamycin phosphate is administered to newborns and infants, appropriate monitoring of organ system functions is desirable.

Nursing Mothers: Clindamycin has been reported to appear in breast milk in ranges of 0.7 to 3.8 μg/ml.

Usage in Meningitis: Since clindamycin does not diffuse adequately into the cerebrospinal fluid, the drug should not be used in meningitis.

SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN AND INTRAVENOUS CORTICOSTEROIDS SHOULD ALSO BE ADMINISTERED AS INDICATED.

Precautions: Review of experience to date suggests that a subgroup of older patients with associated severe illness may tolerate diarrhea less well. When clindamycin is indicated in these patients, they should be carefully monitored for change in bowel frequency. Prescribe with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Do not inject intravenously as an undiluted bolus; infuse as directed in package insert. Indicated surgical procedures should be performed in conjunction with therapy. Patients with very severe renal disease and/or very severe hepatic disease accompanied by severe metabolic aberrations should be dosed with caution and serum clindamycin levels monitored during high-dose therapy.

Prescribe with caution in atopic individuals. During prolonged therapy, periodic liver and kidney function tests and blood counts should be performed. Use may result in overgrowth of nonsusceptible organisms, particularly yeasts. Should superinfection occur, adjust therapy as clinical situation dictates. Clindamycin has been shown to have neuromuscular blocking properties that may enhance the action of other neuromuscular blocking agents. Use with caution in patients receiving such agents.

Adverse Reactions: *Gastrointestinal:* Abdominal pain, nausea, vomiting and diarrhea. (See WARNING box.) *Hypersensitivity Reactions:* Maculopapular rash and urticaria have been observed. Generalized mild to moderate morbilliform-like skin rashes are the most frequently reported of all adverse reactions. Rare instances of erythema multiforme, some resembling Stevens-Johnson syndrome, have been associated with clindamycin. A few cases of anaphylactoid reactions have been reported. If a hypersensitivity reaction occurs, the drug should be discontinued. The usual agents (epinephrine, corticosteroids, antihistamines) should be available for emergency treatment of serious reactions. *Liver:* Jaundice and abnormalities in liver function tests have been observed during clindamycin therapy. *Hematopoietic:* Neutropenia, eosinophilia, agranulocytosis and thrombocytopenia have been reported; no direct etiologic relationship to concurrent clindamycin therapy has been made. *Local Reactions:* Pain, induration, and sterile abscess have been reported after intramuscular injection, and thrombophlebitis after intravenous infusion. Reactions can be minimized or avoided by giving deep intramuscular injections and avoiding prolonged use of indwelling intravenous catheters. *Musculoskeletal:* Rare instances of polyarthritis have been reported.

How Supplied: Available as a sterile solution with each ml containing clindamycin phosphate equivalent to 150 mg clindamycin. Ampoules of 2 and 4 ml.

Caution: Federal law prohibits dispensing without prescription.

SOUTHERN MEDICAL ASSOCIATION DIAL access

the ModiCon balance

TRADEMARK

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in the 28-day regimen contains inert ingredients.

low hormonal content/high patient acceptability

Low hormonal content, yet highly effective
ModiCon combines a low dose of estrogen (0.035 mg ethinyl estradiol) with a low dose of progestin (0.5 mg norethindrone). In clinical trials, the pregnancy rate in **1,168** patients completing **16,345** cycles was only **0.22** per 100 woman-years.

Good patient acceptability with low incidence of amenorrhea and good cycle control†
With ModiCon, the majority of women who start with it stay with it.

Throughout clinical trials, the total incidence of amenorrhea was only **1.0%**. The average cycle dropout rate during the first three months because of menstrual disorders was only **1.2%**.

ModiCon is available in both 21 and 28-day regimens in the unique DIALPAK* Tablet Dispenser.

See the complete Prescribing Information for this product, a summary of which is on the next page.

ModiCon

†Serious as well as minor side effects have been reported with the use of oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be fully aware of the complete Prescribing Information for this product.

ORTHO

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information and patient information before prescribing the product.

INDICATION: CONTRACEPTION. The pregnancy rate in women using conventional combination oral contraceptives (containing 35 mcg or more of ethinyl estradiol or 50 mcg or more of mestranol) is generally reported as less than one pregnancy per 100 woman-years of use. Slightly higher rates (somewhat more than one pregnancy per 100 woman-years of use) are reported for some combination products containing 35 mcg or less of ethinyl estradiol, and rates on the order of three pregnancies per 100 woman-years are reported for the progestogen-only oral contraceptives. Table 1 gives ranges of pregnancy rates reported in the literature for other means of contraception. The efficacy of these means of contraception (except the IUD) depends upon the degree of adherence to the method.

Table 1: Pregnancies Per 100 Women-Years. IUD, less than 1-6; Diaphragm with spermicidal product (creams or jellies), 2-20; Condom, 3-36; Aerosol foams, 2-29; Jellies and creams, 4-36; Periodic abstinence (rhythm) all types, less than 1-47; 1. Calendar method, 14-47; 2. Temperature method, 1-20; 3. Temperature method—intercourse only in postovulatory phase, less than 1-7; 4. Mucus method, 1-25; No contraception, 60-80. **DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES:** Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen. **CONTRAINDICATIONS:** Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Known or suspected pregnancy (see WARNINGS, No. 5).

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.
The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers.
MYOCARDIAL INFARCTION: An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10-to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory diseases may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of oral contraceptives) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The findings of this analysis are shown in Figure 1 below. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The use of oral contraceptives in women in this age group is not recommended. Based on the data currently available, the following chart gives a gross estimate of the risk of death from circulatory disorders associated with the use of oral contraceptives:

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS—RISK ASSOCIATED WITH USE OF ORAL CONTRACEPTIVES

Age	Below 30	30-39	40+	
Heavy smokers	C	B	A	A—Use associated with very high risk.
Light smokers	D	C	B	B—Use associated with high risk.
Nonsmokers (no predisposing conditions)	D	C,D	C	C—Use associated with moderate risk.
Nonsmokers (other predisposing conditions)	C	C,B	B,A	D—Use associated with low risk.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who develop breast nodules should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception.

Figure 1. Estimated annual number of deaths associated with control of fertility and no control per 100,000 nonsterile women, by regimen of control and age of woman.

	15-19	20-24	25-29	30-34	35-39	40-44
No method	5.5	5.2	7.1	14.0	19.3	21.9

Traditional contraception and abortion	0.3	0.4	0.4	0.8	1.4	0.8

4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. Pregnancy should be ruled out before initiating or continuing the contraceptive regimen. Pregnancy should always be considered if withdrawal bleeding does not occur. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. (ORTHO-NOVUM 1/50□21 and ORTHO-NOVUM 1/50□28 contain tartrazine. Allergic reactions have been reported with the ingestion of this dye in some patients.) **ACUTE OVERDOSE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

CURRENT DEVELOPMENTS

Legal and social issues in medical genetics

J. HOWARD TURNER, Sc.D.
T. TERRY HAYASHI, M.D.
DONALD D. POGOLOFF, J.D.
Pittsburgh, Pennsylvania

This paper was written for the purpose of providing the physician with a perspective of the conflicting scientific, individual, and societal interests which have been evoked by increasing medical and scientific innovation in the area of human genetic disease. In it the following subjects are considered: (1) obtaining genetic information by amniocentesis, by genetic counseling, and by screening; (2) disclosure of genetic data to the patient; (3) inclusion of genetic data on the medical record; (4) courses of action available to the individual after disclosure of genetic information, i.e., abortion, sterilization, etc.; (5) the state and involuntary sterilization; and (6) prohibitions on marriage. (AM. J. OBSTET. GYNECOL. 134:83, 1979.)

HUMAN GENETIC DISEASE is rapidly assuming recognition as a major component of the world health deficit. Recent technologic advances now include procedures for the detection of increasing numbers of mutant gene carrier states, genetic defects in unborn children, and formerly unnoticed genetic disease states prior to onset. The need of genetic counseling for prospective parents is assuming increasing importance, and recent indications of behavioral correlates of chromosomal anomalies, if confirmed, will have important social and legal implications.

Each advance in the area of genetic information and procedures raises questions about the rights and obligations of the affected person, his family, and those who counsel and treat him. The very newness of the aforementioned technology has created variable contexts for the balancing of competing and at times conflicting scientific, individual, and societal interests. Moreover, the law's historic and major concern with the balancing of competing interests and resolution of conflicts is highly relevant, and it is obvious that the physician will serve as the major pressure point. Thus, we have prepared this paper for the purpose of providing the practicing physician and other medical personnel with perspectives of a number of relevant social implications and questions associated with genetic disease.

A brief review of basic genetics

Before the governing subjects of this paper are discussed, a short review of basic genetics is deemed to be in order.

It is now widely accepted that the basic morphology, physiology, and biochemistry of an individual are determined by hereditary factors, acting in a relatively specific environment. By the act of reproduction, individuals originate from other individuals similar to them. Inheritance is the transmission of genes, located linearly on 23 pairs of chromosomes, from parent to offspring. The individual members of each pair of

0002-9378/79/090083+17$01.70/0 © 1979 The C. V. Mosby Co.

chromosomes represent homologous types donated by the two parental gametes. Twenty-two pairs are autosomes that determine the majority of the characteristics of the new individual, while the primary function of one pair is the determination of the sex of the individual.

Every individual develops from a basic single cell (zygote) formed by the union of one sperm and one ovum and the subsequent division of this primordial cell into two genetically similar daughter cells which in turn divide repeatedly to eventually form a population of trillions of cells. Therefore, every cell in an individual is assumed to have a "normal" set of chromosomes unique to that individual and similar, in the majority of individuals, to all other members of the species. The genes situated linearly along the length of these chromosomes express their effects through the production of chemical substances which in turn control the essential metabolic cycles of the cell.

It is now possible to select a sample of cells from an individual and, through proper techniques, describe the chromosomal profile of that individual. The number and structure of the chromosomal pairs, i.e., the karyotype, may be different from what is considered "normal" by comparison with an established standard karyotype as determined from large numbers of individuals with no clinical signs of defect. For example in Down's syndrome, or mongolism, microphotography usually notes three Number 21 chromosomes instead of the usual pair. Chromosomal sex can also be determined by observation of the chromosomal pairs. In the female subject, the sex chromosome pair consists of two long, uniquely identifiable chromosomes called the X chromosomes. In the male subject the pair has one long X chromosome and a shorter Y chromosome (always donated by the father). Numerical aberrations of the sex chromosome pair are occasionally noted, e.g., the XYY syndrome in which the individual has two Y chromosomes or Klinefelter's syndrome wherein the karyotype is characterized by two X chromosomes and one Y chromosome.

Obtaining genetic data at amniocentesis performed by the physician

After conception, the growing fetus is surrounded in the uterus of the mother by a liquid known as amniotic fluid. Into this fluid the fetus desquamates cells, most of which are assumed to contain a chromosomal complement identical to that of all other fetal cells. In 1966, Riis and Fuchs utilized this assumption in their study of inherited disease. They called the technique for retrieving fetal cells from the amniotic sac "amniocentesis." To accomplish this, a needle was passed into the fetal sac and a small amount of amniotic fluid gently aspirated. This fluid contained cells desquamated by the fetus and by the inner amniotic membrane.

By careful analysis of the fetal karyotype (following tissue culture in vitro), it is possible to observe architectural or numeric abnormalities which are etiologically related to inherited or congenital anomalies such as Down's syndrome or the sex chromosome syndromes noted above or other deviant phenotypic-karyotypic correlations. Biochemical analyses of amniotic cells following tissue culture in vitro can also diagnose a variety of genetically determined diseases, for example, Pompe's disease (an excess of simple sugars in the cells of muscle and nervous tissue), Tay-Sach's disease (a disorder which has a uniquely high frequency among Ashkenazi Jews) which is characterized by progressive mental and physical deterioration in newborn infants, or Lesch-Nyhan syndrome (self-cannibalism). In all, at least 61 different biochemically based ailments of varied severity can now be detected, and the list is constantly growing.

Amniocentesis as well as its attendant procedures has been refined to the point where some practitioners no longer consider it to be an experimental technique demanding special and rigorous safeguards in its application. Currently, there are no statutes restricting its use where a mother wishes voluntarily to undergo the relatively simple procedure. Therefore, it is now regarded as one of the procedures in the health care–delivery system available to the physician. Like the negligent performance of other medical procedures, breach of a duty the physician owes to his patient, resulting in ascertainable damages, will cause the physician to be liable for malpractice.

One area of potential liability is in the selection of the patients upon whom to perform amniocentesis. Unlike other surgical procedures wherein the patient presents with a specific complaint amenable to x-ray and laboratory testing, amniocentesis elevates personal and family histories to a greater position of importance. Thus, a professional duty may be imposed upon the physician to question the patient in these two areas beyond the normal cursory investigation characterizing most work-ups.

Physicians writing in the field tend to agree that the procedure is solely for the woman with a "high-risk pregnancy." In other words, a woman who has a greater than average chance of delivering a genetically defective child. This group would include couples where one parent is a carrier of a deleterious dominant gene or chromosomal rearrangement. In cases where such chromosomal carrier states are defined, analysis of the amniotic fluid is performed to identify the pres-

ence or absence of genetic disease. The same is true in single gene carrier states when the pattern of mendelian segregation clearly defines elevated probability of an affected fetus. Most young fertile women are defined as low-risk mothers because population statistics clearly indicate that probabilities are high that the fetus will be normal and clearly outweigh the risks inherent in the performance of the procedure and the ascertainment of genetic disease in the fetus. Thus, the procedure is not medically indicated for the majority of the contributors of offspring to the population.

Selection of the proper patient is judgmental with the physician and may be called into question. In the litigative context a physician's judgment is compared to the so-called standard of care. The standard of good medical care is the skill and learning possessed by members of the profession in good standing. As noted, a physician's conduct in a particular situation is measured against what other physicians of the same school would have done in the same or similar circumstances.[1] In the area of amniocentesis the general tenor of the profession suggests the procedure only for the high-risk group. A physician who selects a low-risk woman for amniocentesis breaches his duty to provide his patient with good medical care, since he subjects an improperly selected patient to a procedure for which there is no medical indication. The patient in this case suffers monetary damage in paying for a superfluous procedure and/or may be injured physically, a topic to be discussed below.

After selection of the proper patient for the procedure, the next source of potential liability is failure to procure an informed consent. As in all informed consent situations the actual paper is not as important as the discussion of the procedure and the associated risks and consequences the written form is intended to document. The physician views the signed consent form as protection from liability for untoward results that can arise. Of greater import, however, the consent process, especially in this situation, should expose any misconceptions the would-be parents may have, not only about the actual procedure but also regarding the information the procedure can yield.[2] It is not enough for the physician to state the risks to mother and fetus of the procedure itself. Emotionally, the parents may view a negative chromosomal analysis as insurance that the fetus will be perfect, a view the physician, in his preamniocentesis discussion, must discount.[3]

MacIntyre,[4] in conjunction with attorneys representing his genetic research clinic, devised a consent form for amniocentesis which covers four main areas of possible misunderstanding and potential subsequent litigation. After a brief description of the actual procedure, the form states that there are no guarantees that: (1) amniocentesis will not damage mother or fetus, (2) the attempt to get fluid will be successful, (3) the attempt to get useable cultures will also be successful, and (4) the child born will be normal even if a genetically unbalanced karyotype is found. The signed consent form is intended to insulate the physician from liability for battery, an "unconsented to touching," as well as establish the range of disclosure. Whether or not Dr. MacIntyre's description of the procedure and four-phase discounting of guarantees of success will so insulate the practitioner will depend upon the actual discussion that took place and the theory under which the local court operates as to proof of actual full disclosure. Of course, the consent does not insulate the physician from liability for his own malpractice.

Based upon a survey of the medical literature the potential for malpractice is not remote. If the procedure is done at 12 to 15 weeks of pregnancy, the transvaginal approach—passing the needle through the vagina—is often used. Performance of the procedure in this manner leads to a risk of infection greater than that of the transabdominal approach. Furthermore, the puncture of the cervical wall can lead to permanent rupture of the membrane. After 15 weeks the transabdominal method—passing the needle through the abdomen—is used. The risks to the mother are lessened but, since the amniotic fluid is clear or yellow, it is possible that the bladder may be punctured, producing an aspirate of urine and thus an unsuccessful test.[5]

There are also possible complications during and after amniocentesis whenever the procedure is attempted. That no fluid can be aspirated may mean a failure to reach the amniotic sac or a needle stuck in the fetus. The aspirate may be bloody, meaning an intrauterine vessel has been punctured. Greenish fluid may indicate perforation of the small bowel of the mother. After the procedure is performed, spontaneous abortion may occur due to infection, a traumatic lesion of the uterus, or rupture of the membranes. Fetal death may occur due to puncture by the needle. Puncture of the intestine may lead to maternal peritonitis. Puncture of an intrauterine artery may lead to fetomaternal hemorrhage. In each of these cases where a causal link may be established between the negligent actions of the physician and the untoward effect, the physician has not attained the standard of good medical care. This breach can lead to unnecessary suffering by the patient and necessitate further medical treatment and hospitalization.

After the aspirate is collected it is sent to a laboratory equipped to perform the necessary analyses of the karyotype of the fetus. Failure to obtain only fetal cells

or improper methodology (e.g., a nonaseptic technique) can cause culture contamination, leading to erroneous diagnosis, or require reaspiration. Twinning can cause erroneous results and often, for reasons which are not made clear in the literature, the karyotypes of both parents are not structured, thereby creating a situation where the entire diagnosis rests upon the fetal karyotype. These possibilities, if detected, will make a second amniocentesis necessary. If discovered after the period in pregnancy when the information obtained by amniocentesis can be utilized, such errors of negligence may be actionable as a breach of the contract between the patient and her physician to do an adequate diagnostic test for which the patient has paid.

The above catalogue of errors, which may be due to negligence, is not intended to be a "chamber of horrors" for frightening the medical profession. Nevertheless, the legal implications are obvious when it is noted that, as in other areas of medical therapy, licensing laws have not restricted the use of amniocentesis to a particular group of physicians sufficiently experienced in performing the procedure. Nadler,[6] an eminent researcher in the field of amniocentesis, reported that 1,000 amniocentesis procedures had been done prior to the date of his article's publication in 1971, with no deaths or mobidity. He thus termed the procedure as one of low risk. It must be remembered, however, that these procedures were almost all done by leaders in the field. As the procedure becomes more widely accepted and is performed by more and more physicians the issue will arise whether the standard of care is that of the ordinary competent physician or obstetrician performing the procedure or that of the experts who pioneered the technique. Where the obstetrician or physician performs the procedure he should be held to the standard of care of a specialist with his superior knowledge of the area. This would infer a standard as high as that set by the experts. Where the family physician performs the procedure, he too should be held to just as high a standard since amniocentesis is currently a procedure relatively reserved to the specialist and it would be unfair to the patient to have a less than adequate test performed just because her physician has attempted a procedure arguably beyond his expertise but not beyond his license to practice.

The solution to the problem of keeping the procedure one of low risk, yet allowing increasing numbers of physicians to perform it, will be through the restriction of amniocentesis to the hospital setting and definition of it as part of the privileges of certain physicians such as obstetricians or perhaps even other practitioners evidencing the requisite skill and having access to adequate equipment, e.g., sonography. Furthermore, state statutes regulating the functions of laboratories may aid in assuring quality control and ensuring the production of meaningful tests from the aspirate these laboratories receive. As Nadler suggested, amniocentesis should be done solely by an experienced obstetrician and the fluid sent to a laboratory experienced in culturing amniotic fluid cells and performing the particular diagnostic tests. He[6] wrote: "Because of the risks involved and the consequences of the results (whether or not the physician should suggest the patient have an abortion), only people with a great deal of experience should undertake intrauterine diagnosis."

Obtaining genetic data by the genetic counselor's questioning of his clients

Amniocentesis is a relatively precise method for prenatal ascertainment of a limited number of genetic defects. However, because of the relatively narrow time frame in which it is useful, most genetic data accrue via the more established method of reviewing family histories and establishing pedigree charts.[7] However, two major weaknesses are constant concomitants of this method: First, accurate and detailed family histories are difficult to obtain in any extensive form and second, unlike amniocentesis, interpretation of the data elicited by interviewing is based more on abstract probabilities than on specific knowledge. As an example of this second weakness, the following findings in statistical genetic theory will be helpful. The risk of recurrence of diseases due to abnormal autosomal genes is usually of the order of 25% to 50% of the offspring.[8] The risk of chrmosomal disorders involving visible defects in chromosomes is usually less than 2%.[8] However, if a chromosomal defect is transmissible or if a parent is a carrier, the risk of producing a defective child can be of the order of 20% for each pregnancy.[9] Since the counselor must deal with probabilities of this magnitude, information communicated by these probabilities is often less than satisfactory.

The interviewer who is not a physician, or the particular patient's physician, may be legally precluded from gaining easy access to relevant information contained in hospital records or the records of other physicians, unless he himself obtains a release of information from the patient or from relatives whose medical data may also be highly relevant.[10] A thorough pedigree investigation of a family may be stymied by the privacy rights of individual family members. The law, as yet, does not require that a person make known the fact he harbors a deleterious gene.[10] Thus, the legal issues relating to the interviewer's seeking of information do not concern so much the liabilities he may incur

in gathering his data but the impact of personal liberties regarding privacy which may hinder his thorough search.

Obtaining genetic data by screening

Screening for genetic traits can be done at any time in life. Most often, however, it is advised that screening be done: (1) preconceptually, to check if prospective couples are carriers; (2) prenatally, by amniocentesis as discussed above; (3) at birth or during the elementary school years, so that decisions may be made early enough in life to be acted upon successfully.

Screening programs are often sanctioned by state legislatures. Some programs are on a voluntary basis. In Massachusetts the Public Health Department conducts the Massachusetts Metabolic Disorders Screening Program in cooperation with the Massachusetts General Hospital and the Harvard Medical School.[11] Subject to inclusion are all babies in the Commonwealth for which blood–filter paper specimens are sent to the State Public Health Laboratories from hospitals. When the infant is ready for discharge urine–filter paper kits are given, to be returned one month after birth. The program is voluntary but has very high popular acceptance. The advantages of this system are its ease of operation and the fact that a large data base is being established for future research. This program has apparently gone well since its inception in the obtainment of information pertaining to genetic defects of a biochemical nature. Whether it has made a significant impact upon changing the population's attitude toward voluntary eugenic controls is unclear.

Some state-sponsored screening programs are mandated by law. Among these programs which are primarily concerned with infants and schoolchildren are those designed to diagnose phenylketonuria or the mutant gene carrier state (Hb^AHb^S) of individuals with the so-called "sickle cell trait."

The most widespread mandatory genetic screening procedure is the test for phenylketonuria. The genomic abnormality in this disease entity is responsible for the deficient action of a catalytic enzyme which allows production of an excess of phenylalanine in the body. The buildup of phenylalanine, if unchecked by placing the child on a phenylalanine deprivation diet, often leads to severe mental retardation. As a result of this screening procedure and the use of dietary regimens, the number of retardates with phenylketonuria admitted to state hospitals has consistently diminished. At least one commentator feels the widespread use of phenylketonuria screening is a case of overreaction by state legislatures to what appeared to be an easily explainable phenomenon. Recent studies have disclosed individuals with apparently normal intellects and with blood phenylalanine levels very similar to those of phenylketonuria victims. Yet, these "normal subjects" are placed on the same rigid deprivation diet, the effects of which are not yet fully elucidated.[12]

New York State has recently initiated a screening program among schoolchildren for the purpose of defining individuals with sickle cell trait.[13] The homozygous genotype (Hb^SHb^S) that results in sickle cell anemia is undetectable by amniocentesis and is found primarily in black populations. Approximately one in 400 to 500 neonates is affected. One in 11 to 16 black individuals is a carrier (Hb^AHb^S). New York has devised an obligatory screening program but only for urban schoolchildren. Rural children are screened only at the discretion of the local school physician. Furthermore, due to home-rule legislation, large urban areas such as New York City, Buffalo, and Rochester are exempt from the state legislation. It should be noted that some states have placed sickle cell screening on a voluntary basis or have made it optional on the part of the school physician as part of his routine physical examinations.

Several states have mandatory premarital screening legislation. In California, testing for rubella is a prerequisite for obtaining a marriage license.[14] It is known that rubella contracted by the mother early in her pregnancy can have devastating effects upon the growing fetus. Rubella, however, can only be contracted once in life. The object of the screening program is to determine if a prospective bride has had rubella or whether she should be inoculated against it.

This may be another instance of overreaction by a legislature. The statute was enacted before clinics could be established to perform the tests upon the influx of prospective couples. This situation led the State Public Health Director to instruct all couples to seek court waivers of the test, thus flooding local judicial calendars. The problem has been quickly dealt with and clinics should be ready to meet the demands for tests sometime in the near future.

In 1972, New York enacted premarital screening legislation regarding sickle cell anemia. Screening here is mandatory for applicants for marriage licences who are not Caucasian, Indian, or Oriental.[15]

Professor Linus Pauling has suggested very extensive premarital screening. His proposed legislation would screen all people for heterozygosity for deleterious genes, i.e., all people with a defective gene in a masked recessive state. These people would somehow be conspicuously marked (Professor Pauling does not mention how) and prohibited for marrying another person in the heterozygous state for the same trait.[12] For

a discussion of whether Pauling's prohibition of marriage is possible under our present legal system, see the part of this paper dealing with the courses of action a state may take with the genetic data obtained. The screening provision may be workable, however, whether performed premaritally or at birth.

Screening programs may be subject to constitutional attack. The New York sickle cell screening program for schoolchildren will serve as a good example. Judicial review of this legislation could arise in the following manner. As presently enacted, all urban children are to be tested for the sickle cell trait. The statute does exempt certain children from the procedure but only on religious grounds. Assume that a white youngster whose religion does not forbid such screening refuses to undergo the test or his parents refuse to allow the test to be done on their child. Enforcement of the statute will depend upon its constitutional validity.

However well meaning the New York statute is, cautious drafting may be the cause of its invalidity. A screening program may be enacted under the plenary police power of a state to protect the health and safety of its citizens. A limitation upon the police power is stated in the equal protection clause of the fourteenth amendment of the Constitution. The courts have interpreted this clause as demanding that the state have rational purpose and criteria in establishing a classification of individuals upon whom to apply legal burdens not applicable to others similarly situated. With respect to the New York statute, is residence a reasonable criterion for determining whether or not a child shall be tested? Apparently, the object of the legislators in this case was to avoid racial classification, despite the fact that such a classification probably could evince a compelling state interest to aid blacks. Instead, the law makes the distinction between urban and nonurban schoolchildren for the screening of a noninfectious, inherited disease for which there is no known cure. As in the hypothetical case, it is possible that nonurban blacks may not be screened for the disadvantageous genotype, whereas the urban white youngster will be tested even though he has slight probability of expressing the trait.[16] His refusal may very well be judicially sustained. Despite the understandable caution with which the New York Legislature drafted the statute, the act establishes a bad precedent. In the future the possibility of other screening tests involving ethnic or racial groups is likely. It would seem, within limits, such legislation could withstand an equal protection attack yet still acknowledge a racial or ethnic basis.

Finally, Motulsky[17] has suggested viewing screening from a different angle, not as conceived in legislative enactment but as a component of good medical practice. He has suggested that premarital screening, at least, be made part of the duties of a physician in performing his premarital physical examination. It seems this could apply as well to other physical examinations or pediatric evaluations.

Summary of techniques

Genetic information may be obtained by the physician doing amniocentesis, by the genetic counselor in his questioning of his clients, or by government-sponsored screening programs. To each is attached a certain amount of legal risk. The physician may insulate himself from a suit in battery by obtaining the informed consent of his patient. He cannot, however, relieve himself of liability for his own negligent acts if they cause harm to the patient. Yet, if done properly, amniocentesis is a definitive method of obtaining precise genetic information.

The counselor does not subject himself to a risk of liability as high as that of the physician, yet the information he obtains may be clouded by faulty memories or stymied by recalcitrant sources.

Screening programs have inherent difficulties in that, if they are voluntary, their success in obtaining accurate data depends upon the extent of the popular acceptance of the program. If the screening program is compulsory, care must be taken to avoid possible constitutional attacks, for while the state may have a rational goal in mind in obtaining genetic data it must obtain such data by a reasonable mechanism.

Disclosure of genetic data to the patient

Genetic data about specific individuals may be obtained through amniocentesis, interviewing or screening. Once such data are collected, questions of what findings should be divulged and to whom naturally arise.

As a preliminary precondition for this discussion, the word "patient" must be defined. A patient is anyone who undergoes medical or surgical treatment. In the context of disclosing genetic information the patient is the person from whom data have been collected. Despite the fact that amniocentesis is done to gather data on a fetus, the patient in those cases is the pregnant woman. Finally, while there may arise a duty to disclose information to the parents of a newborn infant or older child, the youngster still remains the patient.

In a symposium held in 1969, in which leading clinical geneticists participated, the question of divulging information to patients, family, and attending physicians was raised.[18] The issue centered around the physician's primary duty to maintain the confidentiality of his relationship with his patient and the fact that, by its

very nature, genetic information often concerns existing relatives and may concern persons who may enter the family in the future.

The concensus was the rather bland statement that information should be disclosed to those who need to know if disclosure does not cause more harm than good. The inference to be made from the statement of the participants was that since disclosure of medical information can often affect the well-being of the patient, and since the law allows the medical profession to establish its own standard of care, this would appear to end the matter.[19] (It must be remembered also that at this juncture the subject is not the amount of disclosure necessary to obtain informed consent for the performance of a procedure, a subject discussed above.)

However, specific answers of the geneticists were quite illuminating. All seemed to agree that relatives could not be told findings related to a patient without the consent of the patient. But as to disclosure to the patient of his own genetic make-up, the physicians noted various areas of nondisclosure. One physician would only divulge information on traits which predispose the individual to biochemical disease and only if that disease could be avoided or ameliorated. Some felt that aberrations of the sex chromosome pair should not be divulged. Others would not divulge information currently thought to be of a psychiatric nature.

As an example of the latter two areas of nondisclosure, the XYY syndrome may be cited. An extended discussion of this genetic defect should give clues as to the reasons physicians are loath to divulge the findings. The XYY syndrome has recently gained much notoriety in the criminal law for its possible implications in a plea of insanity based upon an organic cause by a defendant to show his lack of capacity to form the requisite intent needed to be guilty of certain crimes. Perhaps the most famous case in which the plea was attempted was in the appeal of the murder conviction of Richard Speck who, in 1966, killed eight student nurses in Chicago. Tests done upon Speck "revealed" he had the XYY type of chromosomal complement.[20] Courts are not unanimous in allowing such a plea. In France the plea was allowed. In Australia it was not.[21]

In the mid-1960's Jacobs and associates[22] did a study on men in a maximum-security prison. Of the 315 men tested, nine were positive for the XYY aberration. In other words, whereas normal male subjects have a sex complement of one X chromosome from the mother and one Y chromosome from the father, these men had an extra "maleness" chromosome. Court-Brown and colleagues noted no physical characteristics different from those of other male subjects in these XYY individuals, except that they were taller. Prison records, however, disclosed that onset of criminal activity in these men commenced five years before the average, 90% of which was against property. Court-Brown and associates stated: "This picture strongly favors the idea that the additional Y chromosome genetically predisposes the 47,XYY male to the development of a psychopathic personality and to consequent aberrant behavior and antisocial conduct." However, no studies have shown a direct cause-and-effect relationship between the syndrome and predisposition to crime.

47,XYY fetuses can be discerned utilizing cultured amniotic fluid cells in vitro. The issue then is whether such information when discovered should be disclosed to the parents (perhaps coupled with a recommendation for abortion) or whether euthenic procedures should govern the child's subsequent development after birth in the same way the phenylalanine deprivation diet is suggested after the detection of phenylketonuria. In either case it is difficult on a practical basis to imagine a physician advising that the patient-mother undergo an abortion or that the patient-child be placed on a specific regimen without any explanation as to the reasons for his advice.

In addition to the comments elicited at the symposium most geneticists have been inclined to recommend that neither a child found to be 47,XYY nor his parents be informed of this finding and that no attempt be made to treat the child prophylactically to forestall the emergence of criminal tendencies. The reason for this attitude is based upon an analysis of the population used to detect the syndrome originally, i.e., prisoners. Detractors cite the prison population as being highly unrepresentative. They state that studies show that only 50% of serious crimes are ever reported to the police. Of these, only 12% result in arrest, of which only half of the arrestees are convicted and less than half of the latter number incarcerated.[23] However, specific surveys of 47,XYY children do show them to have a lower threshold for frustration, leading to more frequent tantrums, paroxysmal aggression, unsolicited rage, and, when older, sexual exoticism.[23]

For the physician, the duty he may feel to divulge information as to an XYY child presents a serious dilemma, at least morally, whether to his patient, the child, or the parents. The causal link between the aberration and propensity for crime has not yet been proved although there is some statistical evidence for its existence. The physician can decide not to divulge to the parents and run the risk of serious repercussions, since the child will not be placed in a euthenic environment in which an effort is made to spare the child familial instability, poor parental supervision, and other pressures with which his genetic make-up al-

legedly does not allow him to cope. At least ethically, the physician may be abdicating his duty to provide his patient, the child, with the best possible care. On the other hand, the physician can divulge this information and perhaps by doing so encourage the parents to establish a false and sterile environment for the child in which no natural aggressive behavior is tolerated, perhaps leading to psychological trauma to the youngster beyond that which his alleged XYY constitution would elicit.[23, 24] Disclosure would not be made to the child himself in any event. Physicians would undoubtedly assume such a subject is beyond the comprehension of the patient. More difficult decisions to disclose would naturally occur as the patient-child grew older.

Beyond the debate in the medical world regarding disclosure of findings related to sexual aberrations, some physicians are beginning to question the dissemination of any sex chromosome information. Such disclosures as the gender of a fetus as determined by amniocentesis are rarely crucial to the management of an obstetric case by the physician. In a letter to the *Journal of the American Medical Association,* a Utah pathologist related that a 38-year-old mother of one boy and two girls requested amniocentesis to rule out the possibility of Down's syndrome. The fetus, after testing, was reported to be genetically normal and female. Upon disclosure of this information the parents decided to obtain an abortion on the sole ground that they did not wish another girl. The physician felt that this was an improper use of the knowledge discernible by amniocentesis and therefore should not be divulged.[25]

Guidelines as to disclosure to the patient or relatives, as physicians view them, thus appear to be: (1) reveal to the patient, or his parents if a minor, only what he can grasp and what will not be psychologically damaging; (2) obtain the patient's consent to discuss the matter with the family; (3) encourage or require further genetic counseling for the patient after the information has been disclosed. The suggested guidelines as to disclosure to patient and family would appear to comport with typical duties of the physician to ensure the privacy of the patient. It is debatable whether judgments as to what information to withhold could stand judicial analysis when based upon a physician's perceived notion of the psychologically damaging nature of his disclosure.

As reflected by the comments elicited by the participants at the symposium, physicians appear to be laboring under the notion that disclosure problems should be resolved in favor of the foremost responsibility of a physician to his patient, i.e., doing what is best for the patient. They appear to believe that this may be discerned by what is considered good medical care as determined by the profession itself. This may be not the view of the public and the law.

Generally, the issue of disclosure arises in the litigative context in cases alleging failure of the physician to obtain informed consent for a procedure, thus rendering the physician liable in battery after the procedure has been accomplished with an untoward result. The patient argues that the freedom of choice was limited by the physician. In such a case, the patient asserts that he was denied the right to make an intelligent decision whether to consent or to refuse to undergo the procedure or to choose other possible options due to the physician's alleged omission to state all the pertinent facts regarding the intended treatment.[26]

In the case of *Nishi vs. Hartwell,* 473 p 2d 116 (Hawaii, 1970), a malpractice action was predicated on the fact a physician did not alert his patient to the collateral risks of an intended surgical procedure. The patient's widow argued that such an omission obviated the possibility of the patient's giving informed consent and thus rendered the physician liable in damages for battery after the operation had taken place. On appeal the physician prevailed. He argued in defense that disclosure of the collateral risks of the surgery would have caused the patient great apprehension and thus aggravated a pre-existing condition which the procedure was intended to diagnose prior to definitive surgical intervention. The court allowed the physician to introduce evidence as to the standard of care in the medical profession regarding disclosure in such a situation by his own testimony. This apparent infringement of the patient's freedom of choice by the physician represents a departure from the basic rule as cited above.

Whether courts will extend the physician's standard of care as the absolute criterion in situations not immediately involving the physical well-being of the patient is arguable. To explore this one must look at the two alternatives available to the physician regarding disclosure. What are the litigative possibilities if a physician does divulge genetic information to a patient or the parents in the case of an infant or fetus? Let us use the above-noted examples of findings of 47,XYY. To be liable in malpractice the physician must breach a duty to his patient, causing the patient harm and damages. The physician may well feel he has breached his duty to his patient for stating a fact that may be psychologically damaging. However, it is difficult to see the harm the patient has suffered. Perhaps the revelation will be startling but it is hard to conceive that stating a fact to a patient will be actionable as the infliction of emotional distress, for instance, except in the most extraordinary of circumstances.

Many disclosures made by a physician to a patient are distressing; they range from telling a patient he has an incurable disease to revealing the finding of hemorrhoids. None of these has of itself been found actionable by the courts. The important element not found in these cases is so-called foreseeability. A patient may suffer harm after disclosure that he harbors the 47,XYY trait, for example, by committing suicide. It is inconceivable that the physician will be held liable for such harm due to this disclosure unless this result was foreseeable by the physician. In the *Nishi* case the evidence of the standard of good medical practice revealed that severe aggravation of a pre-existing condition would be a foreseeable consequence of disclosure. Nevertheless, this must be seen as an extraordinary situation.

On the other hand, assume that the physician takes it upon himself to omit findings he has made, presumably for the reason that they may be traumatic. On a purely practical level, once the patient does discover these facts, it is possible his trust in his physician will be irreparably shattered unless the physician convinces him nondisclosure was for the patient's own good. In the legal context, it may be true that in the absence of a battery action based on the lack of a fully informed consent the patient may not have an action due to lack of damages, but it is not difficult to picture a patient who is seeking injunctive relief parrying for full disclosure by his physicians. Patients have the legal right to review their medical records when kept in hospitals.[26] Extending this to all findings of a physician is not inconceivable. In the future amniocentesis may be restricted solely to the hospital setting. The right of patients to know all the results of such tests should be further reinforced by the American Hospital Association's Patient's Bill of Rights of which the patient's right to know is a firm precept.[27]

Physicians may argue that a little learning is indeed a dangerous thing. They may say that disclosing such findings as sexual aberrations or the gender of a fetus as found upon amniocentesis should add nothing to the information needed by a patient to make a decision, in this case to seek an abortion. If anything, the medical profession could argue, such disclosures lead to nothing but unwarranted controversy and confusion. On balance, the right of the patient to know about findings pertinent to him must outweigh a physician's perceived notions as to the effect of his disclosure, except, of course, as noted above, in that instance where severe physical distress will follow the disclosure and is foreseeable. It must be underscored that to be actionable the infliction of foreseeable distress must be upon the patient. It would be extremely unlikely that this would allow parents to sue following alleged revelations regarding their child.

Inclusion of genetic data in the medical record

A more delicate subject involves the inclusion of genetic information in the medical record. Despite the confidential nature of the record to those outside the health care–delivery system, this is often not the case for professional eyes within the system. Opinions of geneticists are mixed. One extreme is the statement that the scientific value of having accurate records and being able to exchange data thereon with other researchers far exceeds the consideration of protecting the rights of the individual patient. Other commentators would again segregate sexually and psychiatrically based data into records inaccessible to all but the attending physicians either on sheets to be removed in the record room or in private computer banks. This would prevent accidental release of information to insurance companies or other agencies which could cause the patient to be under a social debility. One physician would require removal of such data should the record be subpoenaed. The legal basis for this latter recommendation appears extremely murky since once in the record, and with the assumption the patient has consented to the release of information in his record, no privilege is available to the hospital for retaining such information in secrecy. If the law allows the patient to see his own record, it must follow that the record must be shown to anyone the patient designates.

Most physicians feel that genetic data should be treated precisely like the traditional family or personal history is treated. Information included should primarily be related to the provision of an adequate diagnosis with other information only being included at the discretion of the physician. This latter view again appears to comport with traditional duties and responsibilities of a physician to his patient. To this opinion one physician added a suggestion applicable to all medical records. He stated that with the increasing mobility of patients today and the lack of continuity of the doctor-patient relationship, the medical record should be given to the patient with an additional requirement that the physician provide a statement regarding observed genetic defects which may be genetically transmissible. A physician doing so will incur no legal liability, as noted above, except, of course, in that rare case when disclosure will lead to foreseeable harm to the patient.

Disclosure of genetic data to third parties

The physician has an ethical duty, as noted previously, not to disclose information he has gathered

about his patient. This duty is probably not breached if a particular patient's genetic data is published in a research journal as long as the patient's identity remains anonymous and the data are related to the study.

Other disclosures to third parties without the patient's consent may be legally actionable if the patient has been harmed. Defamation is defined as a written or oral communication to a third party tending to injure the reputation of the person defamed. Truth is an absolute defense in a defamation action. However, assume for the moment that the finding disclosed to the third party about the patient was erroneous. For example, a patient could predicate a suit in defamation against a physician or genetic counselor who discloses the erroneous fact the patient has an 47,XYY constitution to the patient's relatives, friends, or governmental or social service agencies without the patient's consent, in the hope that these parties will attempt to aid the patient. The patient may argue that his reputation as a peace-loving citizen has been damaged. The physician or counselor may respond that he has a qualified privilege for his actions, thus barring a defamation action since his disclosure was justified to establish a euthenic environment for the patient. Justification as a defense of defamation usually involves disclosures necessary to protect the community such as disclosure of a patient's contagious disease. The case of *Simonsen vs Swenson*, 177 NW 831 (Nebraska, 1920), presents a good example of this. In this case the physician disclosed to this patient's landlady the finding of contagious venereal disease. The landlady subsequently evicted the patient. The court found that the communication fell under the qualified privilege of disclosure to third parties. However, the court did state that, in the absence of such a privilege, the physician could have been found civilly liable for his action since betrayal of a professional secret to the detriment of a patient was a ground for revocation of a physician's license and a breach of trust. Whether something so speculative as the threat of an aroused 47,XYY individual to the community is sufficient justification for the disclosure of such data may be debated.

Where unauthorized disclosure has been made, the patient may also base a suit upon damages caused by invasion of his privacy. A physician or counselor who commercially exploits a patient's genetic defect(s) will probably be held liable for causing the patient humiliation and unwarranted public exposure. The key to an invasion of privacy action is unjustified placement of the patient in the public spotlight. Disclosure to family members probably will not satisfy this requirement. Disclosure to governmental or social service agencies such as community mental health organizations may come closer to satisfying this requirement to predicate an action or invasion of privacy.

All physicians at the symposium agreed with the general statement of the law that beyond disclosure to patients, recording upon the chart, or publication in research journals where patient anonymity has been assured, privacy precludes revealing genetic information to any other sources without the patient's consent, unless there exists specific legislation based upon sufficient data to show that the need for dissemination of the information outweighs personal rights of privacy. This should apply even to public health screening programs that release information to other governmental agencies.

As a final comment regarding disclosure to third parties, professional or otherwise, one professor would divulge information only if the recipient is trained to influence the behavior of the individual concerned, the family, or the physician. The recipient, he stated, must have a thorough knowledge of the total impact of the genetic situation in terms of emotional, social, and financial aspects. He stated that the family physician himself often does not possess this competence.[18] Perhaps this geneticist would only disclose information to experienced genetic counselors. While this may be a good suggestion from a sociologic and scientific viewpoint, this would appear to breach the right of privacy of the patient as well as the patient's right-to-know data pertinent to him in an uncensored manner.

Courses of action available after disclosure of genetic data to the individual

Abortion after amniocentesis. Today, if full disclosure of the findings of amniocentesis to the patient-mother is assumed, the current state of medical progress allows individuals only two alternatives should genetic defects be discovered: do nothing and produce and care for a child who may or may not be defective or seek an abortion. In two cases: *Roe vs Wade*, 93 S CT 705, 1973, and *Doe vs Bolton*, 93 S CT 739, 1973, the United States Supreme Court laid down guidelines concerning the extent to which states can regulate abortion. In the first trimester of pregnancy the state may not regulate or prohibit abortion. This decision is based upon the patient's right of privacy. The United States Supreme Court found this to be a fundamental concept of personal liberty as guaranteed by the due process clause of the fourteenth amendment. In the second trimester the state may enact statutes intended to protect the health of the mother. In the third trimester a state can regulate abortion, or even prohibit it, except where abortion is necessary to preserve the life or health of the mother.

Within this legal framework it would be wise to explore the specific medical situation. At least one case has held that there is no established standard of care when advising the mother of a potentially defective fetus to undergo an abortion.[29] The usual advice given if the amniocentesis reveals a significant genetic defect is that the woman should procure an abortion. Given the time needed for development of the cellular cultures and making the chemical assays and photograph (usually 2 to 4 weeks), the physician is upon the horns of a dilemma. He can advise the amniocentesis early in pregnancy, risking greater chance of infection, etc., but leaving greater time for the analysis or reaspiration in case of failure. On the other hand, he can wait until the fifteenth week, lowering the risk of untoward results from the procedure itself, yet perhaps allowing insufficient time to obtain an abortion if the results are delayed but positive.

Fuchs, co-developer of the technique, has stated that amniocentesis should never be carried out unless the parents are willing to act upon the results. If the parents are willing seriously to consider abortion upon disclosure of positive results such facilities must be readily available. The recent Supreme Court cases cited above forbid state regulation of the use of abortion but conscience clause legislation may militate against this. In one of its opinions the Court left untouched a section of the Georgia statute which stated that private hospitals and their health personnel could refuse to perform an abortion if doing so violated their consciences.[29] Thus, abortion on demand has not become a reality and delay in finding readily available facilities, aside from patient inconvenience, has medical implications as well. Medical authorities agree that the abortion after amniocentesis should be done no later than the second trimester, weeks 12 to 24 of the pregnancy. As noted, the Supreme Court cases allow second-trimester abortions but states can still restrict abortions after this time period. This places the amniocentesis and subsequent abortion on a rigid time schedule, allowing little margin for error or delay in the results, since the optimum time for the amniocentesis is at 15 weeks.

Another matter is the impact of erroneous results. If the results of the tests are reported as positive for a genetic defect but are, in fact, erroneous, an abortion may be procured and the products of conception may be found negative for genetic defects. Here the physician may be in a delicate position. He can stand upon his statement of prior reservations as to guarantees, if he has noted these in the consent form and made them clear in his discussion prior to amniocentesis. This, of course, will not insulate him from liability if the erroneous results were caused by his own actions which fell below the standard of care for the procedure. The possibility of a wrongful death action may be considered by the parents but is of doubtful success, given that the Supreme Court refused to resolve the issue of whether such a fetus is a constitutionally recognized "person."[30]

At the other extreme is a reported negative result but the baby born is malformed or biochemically defective due to genetic defects which could have been noted by the assays following amniocentesis. Again, the parent's suit in malpractice may be entertained if the doctor or the laboratory has not achieved the standard of care in the field. Militating against this is the requirement that the parents show that because of this breach of the standard of care they have been harmed in a manner the law recognizes.

Suits for wrongful life have been tested judicially. In an area unrelated to this present topic but giving a clue as to judicial thought in this situation, the child born out of wedlock brought a damage claim against his father for emotional distress. The Illinois Appellate Court in *Zepeda vs Zepeda,* 190 NE 2d 849, 1963, denied the claim: "Encouragement would extend to all others born into the world under conditions they might regard as adverse."[31]

Four years later, the New Jersey Supreme Court was faced with a problem dealing directly with wrongful life and alleged medical malpractice. In *Gleitman vs Cosgrove,* 227 A 2d 689, 1967, a mother contracted German measles one month after conception. She told her physicians of this condition and they stated that it would have no effect upon the delivered child. Claims were asserted on behalf of the child and the parents since the child was born with severe speech, sight, and hearing problems. The New Jersey Supreme Court rejected all claims. As to the child, the court found no cause of action since, absent the negligence of the physicians, the child never would have been born.[32] The court's reasoning followed *Zepeda* in disallowing any claim for damages for adversity of birth, assuming no malpractice leading to prenatal injury. As to the parents, the court found the decision against them necessitated more extensive discussion. The parents had argued that the emotional impact of rearing a defective child would have been eliminated had the physicians told them the true extent of the possible fetal disability. Had they known, the parents contended, they would have sought an abortion, which, according to New Jersey law at that time, would not have been a criminal act under the circumstances. The court rejected this claim on the grounds that damages in this case would be difficult to measure.[33]

On a more philosophic level, the court went on to state that it would be against the public policy to compensate for the failure to take a fetal life, despite the fact an abortion would be legal. The court went on to note the various famous personages who suffered from hereditary or congenital handicaps and overcame these to lead productive lives. If given the choice, the court reasoned, an individual would rather live with defects than have no life at all. The right to life thus outweighs any emotional or financial burden upon the parents. At least as to wrongful life judicial opinion would appear to insulate the physician or laboratory from liability for errors in the results of amniocentesis.

Other jurisdictions have also rejected this type of action. In *Stewart vs Long Island College Hospital,* 283 NE 2d 616, 1972, recovery was denied a patient for a hospital committee's failure to advise a patient that the fetus was defective and abortion indicated. The hospital was successful in its argument that the law did not recognize the idea of wrongful life. In *Wilmington Medical Center, Inc. vs Coleman,* 298 A 2d 320 (De Sup Ct, 1972), a pregnancy ensued after the failure of a tubal ligation for sterilization purposes. Again, the court here did not recognize a case predicated on wrongful life since damages would be too speculative of definition.

This, however, is not to say that another court may reach a different opinion. Parents availing themselves of amniocentesis should be granted relief if, by negligence, a defective child is produced. Many articles in the medical literature concern indications of a defective fetus and the magnitude of these defects. A standard of care should be developed for determining when an abortion should be advised and when it should not. Also it should not be enough for courts to list the famous people who suffered from genetic diseases or defects and overcame them. Apparently, many courts are stymied in regard to determining damages since costs of raising a defective child could be offset by the child's future productivity.[34] Many genetic defects produce individuals who can be nothing but a burden to themselves, their families, and society. Their potential usefulness or enjoyment of life is nil.[35] It should not be beyond the scope of a court to determine the financial burden of rearing such an individual since offsets are not involved. Many defective children are placed in state-run institutions. In these cases the financial burden (and damages possible in a court action) is lessened. This may be the mechanism by which parents can be entirely relieved of the economic hardship of caring for such a child.

Voluntary sterilization. Voluntary sterilization, whether or not as a means of genetic control, is not forbidden in any state.[26] Some states do regulate it somewhat in terms of age of the patient or the requirement that a doctor perform the procedure.[36] Other states which had forbidden voluntary sterilization except when a medical necessity have repealed such acts.[37] In *Jessin vs County of Shasta,* 274 Cal App 2d 737, 1969, the court found voluntary sterilization to be constitutionally protected from infringement by the state under the right to privacy. Voluntary sterilization is also no longer considered a form of mayhem in depriving oneself of the ability to fight for his sovereign.[38]

Griswold vs Connecticut, 381 US 479, 1965, has probably prevented the possibility that a state could make it criminal for an individual to advise sterilization as a means of postmarital contraception, based upon the right of privacy.[39] *Eisenstadt vs Baird,* 92 S Ct 1029, 1972, has probably done the same when advising unmarried individuals. In the latter case, the United States Supreme Court upheld the Court of Appeals which had reversed a felony conviction of a person who had dispensed a nonprescription contraceptive foam after a lecture at Boston University on population control. Baird had dispensed such foam to unmarried women in contravention of a Massachusetts statute. The Court found that the right of privacy protects all individuals, married or single, from unwarranted governmental intrusion into matters so fundamentally affecting a person as the decision whether or not to bear or beget children.

Whether there is a right to voluntary sterilization on demand will probably depend upon whether the institution at which it is sought is private or governmental. In *Hathaway vs Worcester Hospital,* 72-1114, First Circuit of Appeals, 1973, the court cited the cases of *Eisenstadt, Roe,* and *Doe* and stated that, "We are merely saying that . . . once the state has undertaken to provide general short-term hospital care, as here, it may not constitutionally draw the line at medically indistinguishable surgical procedures that impinge upon fundamental rights. Accordingly, we reverse (the district court's dismissal of the action) and remand for entry of an order declaring the Worcester City Hospital's policy against the use of its facilities in conjunction with sterilization operations is unconstitutional."[40] Private hospitals though can determine their own policies with regard to sterilization.

The state and involuntary sterilization. Negative eugenics is a conscious attempt to reduce the number of deleterious genes in the gene pool.[41] Involuntary sterilization statutes are examples of legislating negative eugenics. By their application such statutes prevent certain individuals from procreation. The right of procreation is not mentioned in the Constitution but

decisions of the United States Supreme Court have stated that this, nevertheless, is a fundamental right.[42] The due process clause of the fourteenth amendment of the Constitution protects citizens from unwarranted infringement of fundamental rights by states. For a state to abridge a fundamental right it must have a compelling interest.[43] The state is also required to achieve its goal by rational means. The state could argue that its legislation seeks to improve the quality of life by reducing the number of individuals who suffer and are burdensome to others. While this may be a compelling state interest the means used may be attacked as being based on a distinct paucity of scientific evidence.[44] Mental retardation, for instance, due to a genetic defect, is often a recessive condition. To be expressed in the offspring of a retardate means the sexual partner must also carry at least one similar defective gene, often an extremely rare occurrence. If the mental retardation is due to a dominant trait this would appear to strengthen the rationale for sterilization since procreation with any partner would have a high a priori probability of producing a similarly affected offspring. However, mental retardation that is dominant is not only extremely infrequent but also highly likely to be associated with other genetic debilities usually rendering the possessor incapable of reproduction. Thus, except in the case of individuals whose mental defect is caused by a dominant gene and who are capable of reproduction, the preclusion of procreative potential appears an irrational legislative method of obtaining an arguably rational goal of preventing the genetic transmission of defects.

The legislative bases for sterilization laws often include the provision that sterilization is for the ease of caring for a defective individual and the prevention of irresponsible parents whose children often must be cared for by the state.[45] Earlier decisions found involuntary sterilization an exercise of the police power not offending constitutionally guaranteed due process. The Kansas court found its sterilization statute in the public interest.[46] Idaho and Nebraska found this use of the police power applicable as a way of furthering the good of the community as a whole.[47, 48] The Michigan court stated that, "No citizen has any right (to procreate in this case) superior to the common welfare."[49] The United States Supreme Court validated this power in the celebrated case of *Buck vs Bell,* 274 US 200, 1927.

While sterilization statutes remain on the books the judiciary in many states is slowly turning away from frequent utilization of such statutes, often on procedural grounds. In *Frazier vs Levi,* 440 SW 2d 393, 1969, the mother of a retarded girl petitioned the court for her daughter's sterilization. The Texas court denied her request, stating that an incompetent ward does not have legal capacity to make such a petition and her guardian does not have legal authority. This decision thus restricted petitions for sterilization to state agencies. Some states, however, would allow a natural guardian to consent just as for other medical procedures.[50] A question to be raised here is whether a physician would perform the procedure, even with the consent of the guardian, without further assurances that the consent will not be found invalid at a future date and possibly render the physician liable for an "unconsented to touching."

Not all courts are retreating from involuntary sterilization legislation. The case of *In Re Cavitt,* 157 NW 2d 171, 1968, from Nebraska, should be noted. Here, the mother of eight children was confined to an institution for the mentally deficient. Sterilization was made a prerequisite for her release.[51] According to the Nebraska statute a Board of Examiners of Mentally Deficient made up of five physicians from state hospitals is delegated the power to decide if sterilization is necessary for release from an institution, based on its psychiatric evaluation of the patient (to determine if the patient is mentally defective) and its physical examination of the patient (to determine if the patient is capable of procreation). After the procedure is performed, witnessed by a member of the Board, certification of the sterilization is placed in the public records of the State Department of Health. The Nebraska Supreme Court upheld the statute in a curious three-to-four decision. (The Nebraska procedures acts require that for the state supreme court to rule a statute invalid there must be the concurrence of five of the seven justices.[52]) The three justices did not find an unlawful delegation of power to the Board. Their opinion further stated that mandatory sterilization in this case was a valid exercise of the police power. While acknowledging that procreation is a fundamental right, the three found its infringement was based upon a compelling state interest in furthering the good of the community. Finally, in a statement that militated against the presumption that the statute was, in part, based upon genetic considerations, the court held that it would not be necessary for the state to demonstrate that children born to this woman would inherit her mental subnormality.

Due process guarantees must be complied with in sterilization cases and are included in most sterilization statutes. These consist of the following: (1) A hearing must be held; (2) adequate notice of the hearing must be given the candidate; (3) a guardian must be appointed if the candidate does not have one.[53] Since individuals subject to involuntary sterilization are often indigent and of necessity incompetent, by analogy to

juvenile law, right to counsel may also be required.

The United States Supreme Court has not reviewed this area since *Buck vs Bell.* Since the time of that opinion the scientific basis of involuntary sterilization as a method of eliminating deleterious traits has been weakened.[54] The Court's subsequent and repeated pronouncements on procreation as a fundamental right may make a state's proof that it has a compelling interest for infringing upon this right and a rational method to do so a most difficult task.

In *Holmes vs Powers,* 439 SW 2d 579, 1969, the Kentucky court held that where the state has no sterilization statute and the would-be patient is incompetent she herself cannot legally consent to the procedure. In the absence of statute, a court order is not enough to insulate the parties from liability for an involuntary sterilization. A graphic example of this is the case of *Wade vs Bethesda Hospital,* 337 F Supp 671 (DC3D Ohio, 1971). Here, the court found a state probate court judge personally liable in damages for ordering the compulsory sterilization of an incompetent minor. The judge pleaded in defense that he must be granted immunity from suit since he, at most, exceeded his jurisdiction. The court found that in the absence of enabling legislation the judge had no jurisdiction at all over this matter and, therefore, was not immune. As dicta the court added that, although Ohio had no statutes forbidding sterilization, bills proposing compulsory sterilization for incompetents had arisen at numerous times since 1925 in the legislature and had been consistently defeated. Therefore, the judge had no legal authority to act upon the petition of the local county welfare board.[55]

The final determination of this case did not include the hospital or the physicians who performed the surgery. It is possible that these parties settled out of court. The complaint of the plaintiff did suggest a possible ground for liability on the part of the hospital and the physicians. The complaint charged a conspiracy by all parties to deny the plaintiff her civil rights (as codified in 42 USC, 1983) under cover of state law by seeking the aid of the state probate court judge in furtherance of their scheme.

This last issue of the potential liability of health personnel in the field of genetics raises a good point. In the minds of most physicians doing what is best for the patient is of primary importance. Motivated by this goal, disclosures may be made to inappropriate persons or, as in the *Wade* case, sterilization may be sought. It is highly probable that in an effort to aid the patient physicians may not realize they are performing acts to which legal sanctions attach. No aspersions should be cast upon medical altruism. It is, however, imperative that physicians become aware that they operate in a legal as well as a medical framework and that medical goals must be seen in the light of the legal safeguards of personal liberty.

Prohibitions on marriage. States have also enacted statutes prohibiting the marriage of certain individuals, again presumably partially based on genetic considerations. For instance, Washington and North Dakota prohibit the marriage by a woman under 45 or a man at any age, unless he marries a woman over 45, if either one is imbecilic, insane, a habitual criminal, a common drunkard, or feebleminded or has hereditary insanity.[56] As with most negative eugenics legislation, the scientific basis for the statutes is weak. Criminality and drunkenness have not been shown to be inheritable. Even scientists who believe the 47,XYY syndrome can cause aggression and consequent criminal behavior are aware of the limited possibility that 47,XYY can be genetically transmitted and expressed in an affected individual's offspring. Perhaps the inclusion of these traits is a reflection of the legislature's notion that these people would become poor parents. But the statutes are silent as to when statutes such as noted above are gained or lost. Due process guarantees in the Constitution demand that statutes be written with sufficient clarity and exactness as to be capable of specific application. It would appear that these acts are vulnerable to constitutional attack for vagueness and overbreadth. Besides this, nothing in the statutes prevents procreation by the named classes of individuals without the benefit of marriage.[57]

All states ban marriages between members of a direct lineal line and 30 states extend this to prohibit marriages of first cousins.[58] Presumably these statutes are grounded upon medical evidence that the offspring of such unions tend to be genetically inferior. While such evidence has been questioned there is no trend toward easing such restrictions. Furthermore, these restrictions are often reinforced by incest statutes which carry severe penalties. Genetically it is true that by virtue of common ancestry recessive genes of both partners will have a greater statistical probability of expressing themselves. By the same token if the ancestry is sound the child of such a union receives a double genetic benefit. Thus, it is not the consanguinity of the parents which causes a defective offspring but the presence of a deleterious recessive gene in the ancestry. The question must be asked again whether a state can show a compelling interest for infringing upon the right of lineal descendants or first cousins to marry and procreate and, if it does, whether its method of achieving this goal is rational. Like involuntary sterilization legislation, prohibitions on consanguinous marriages based

purely on genetics rest on weak scientific evidence where the genealogic records of the prospective mates are free of deleterious influences.

Another legislative attempt to prohibit marriage is the antimiscegenation statute. This type of legislation is based upon the fallacious assumption that positive genetic characteristics of any race cannot be achieved if the races are mixed. The United States Supreme Court in *Loving vs Virginia,* 388 US 1, 1967, held such legislation unconstitutional because such a legislatively created racial classification was without a compelling state interest. At least one commentator feels that banning such negative eugenic statutes as this advances the state's goal of eliminating deleterious traits, if not deleterious genes, by providing for the introduction of new, advantageous genetic combinations into the gene pool.

Conclusion

More and more genetic information is being obtained about specific individuals through amniocentesis, interviewing, and screening. Despite the fact that physicians currently feel certain findings must be kept confidential, for the most part patients will become aware of their individual genetic complements. The receipt of such knowledge imposes duties and responsibilities upon the recipient to act upon such knowledge. Data collection qua data collection would appear a futile exercise of scientific curiosity. The final question of this paper then must be whether a price must be exacted for the genetic information an individual receives, solicited (amniocentesis or interviewing) or not (screening).

At present, it appears that as long as there is a fundamental right to procreate the possibility that a state-sponsored eugenic program will become a reality is very small. Negative eugenics programs in existence today, as noted above, are not effective as a method of eliminating deleterious traits in future generations because of their poor scientific bases.

Positive eugenics programs would go beyond the goals of negative eugenics and seek to ensure that superior genes would be propagated. A program such as this would involve the encouragement of people with so-called superior genes to procreate via marriage and the discouragement of the marriage between individuals with "inferior genes." While such a goal may arguably be within the purview of the state to maintain and improve the health and welfare of its citizens, any compulsion to such a goal would be vulnerable to constitutional attack. Due process guarantees in the Constitution prohibit the infringement of fundamental rights without a compelling state interest. A positive eugenics program would have to prohibit the procreation of certain people deemed inferior. Positive eugenics sits upon scientific bases even more speculative than those of negative eugenics. It is doubtful a compelling state interest could be predicated on such a notion.

A positive eugenics program would also involve classifying individuals according to their genetic make-ups. Chief Justice Burger has said that in applying the equal protection clause of the fourteenth amendment to exercises of the state police power, the Supreme Court will check to see that the criteria for placing people in different classes are reasonable and not arbitrary, with the goal of the legislation kept in mind.[59] Determination of traits in order to classify individuals would appear at present fraught with unreasonableness and capriciousness. Since man is a complex physical and intellectual entity, a selection process not offensive to constitutional guarantees appears an insurmountable dilemma. Even if traits to be selected are scientifically neutral subjectivity will enter the picture through the social judgments of the selectors. The late Professor Herman Muller, a Nobel laureate in genetics, member of the Columbia University genetics group, and advocate of positive eugenics legislation, provides a good example of this. His lists of attributes he felt should be propagated were creative intelligence, a cooperative disposition, and robust health. Yet the famous personages he felt met these standards kept changing with the professor's political alterations from Lenin and Marx in his early career to Lincoln and Descartes as he grew older.

The uses of genetics must be viewed in the light of constitutional guarantees afforded all citizens. Fundamental rights as currently enumerated by the United States Supreme Court must be protected from unwarranted infringement by states. People must not be classified by means of arbitrary and scientifically speculative criteria. Other rights not found specifically in the Constitution must be respected as well. While patients must have a right to know data pertinent to them their privacy must be protected from unwarranted invasion.

With such a legal framework as currently exists the best approach in dealing with genetic information and the best method of bringing about the utilization of such data would appear to be the exertion of peer pressure after the citizenry is educated as to the burdens of rearing a defective child and the means to prevent it. This does not necessarily mean that society should encourage all carriers of deleterious genes to seek voluntary sterilization. Few people exist who are not carriers of some defective traits, usually in a masked recessive state. This does mean, however, encouragement of

judicious application of screening, counseling, and amniocentesis.

Cystic fibrosis can serve as a good example of this. Premarital screening can detect those individuals who carry the recessive gene for cystic fibrosis. These people could be advised of the defect in hopes their choice of mate will reflect this information. If the chosen mate was recessive for the cystic fibrosis trait, then amniocentesis could be helpful after conception to determine if the fetus was definitely affected. By combining these two procedures, the carrier couple, assumedly more enamored of each other than of cytogenetics, could still plan for a normal family with abortion eliminating the risk of producing children with cystic fibrosis. The final choice, of course, must be left to the individuals themselves. But if wise choices are not made the genetic price to be exacted later may be astronomic.

In closing, euthenics, the science of making the environment or living conditions better, especially for those with defects, must be discussed. An obvious example of euthenics is providing eyeglasses to people with poor vision. Euthenics is a function of a more and more sophisticated and compassionate society which sees help to the disabled as a public policy. While only the most callous would take issue with the progress of our society in this matter, euthenics often runs counter to another notion, stability and evolution of the gene pool. It may be difficult to enact eugenics legislation despite the fact that, however misguided, it is aimed at eliminating deleterious traits while enabling beneficial traits to abound. Euthenic legislation is much easier to enact, but its effects can be negative. In the short run, euthenics is often very expensive.[60] In the long run, euthenics can potentially lead to genetic deterioration.

Natural evolution tends to remove defective genes from the gene pool by removing individuals with these genes before the reproductive ages, through death. Public sentiment which encourages the granting of aid to medical research has the ultimate effect of keeping such individuals alive and comfortable well into the reproductive years, allowing them to transmit their deleterious genes. The diabetic patient, the hemophiliac patient, and many types of people with genetic biochemical imbalances today all have the opportunity for a normal existence. The prolongation of the lives of these people is an asset to society in the potential productivity of these individuals. However, repeated transmittal of their defective chromosomal complements may so increase the genetic load in man (the deleterious genes that he carries) as to irreparably weaken the species. Currently, the thought of curtailing euthenic activities would appear barbaric. It must be hoped that soon the popular appeal of euthenics can be at least partially channeled into eugenics before man's science and compassion are the cause of man's undoing.

Information for authors

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

COMMUNICATIONS IN BRIEF

This section is suitable for reporting results of therapeutic trials, descriptions of new procedures or instruments, and case reports which illustrate a principle. Reports should be limited to seven hundred words and two references. Use of an illustration or table requires a proportionate reduction in total words.

Ultrasonic detection of combined pregnancies

RICHARD B. KURZEL, PH.D., M.D.

Department of Obstetrics and Gynecology, State University of New York at Buffalo, Children's Hospital, Buffalo, New York

COMBINED INTRAUTERINE and ectopic pregnancies have always been felt to be a rare occurrence, with an estimated incidence of 1 in 30,000 pregnancies.[1] However, reports in the literature of combined pregnancies have increased and a survey by this author notes 549 such cases reported to date. A suspicion that this entity is under-reported and probably underdiagnosed is supported by the extreme difficulty in making the diagnosis of a combined pregnancy on clinical grounds. The patient usually presents with symptoms which turn one's attention to the presence of an ectopic pregnancy; however, the absence of vaginal bleeding can be a clue to the presence of an intrauterine pregnancy during the first trimester. Clinical criteria for making the diagnosis were reviewed by Winer, Bergman, and Fields[2]; in their series the correct diagnosis on clinical grounds was made in only 9.9% of the cases. Most often, suspicion of the presence of an intrauterine pregnancy first appeared only at the time of laparotomy. Two cases of combined pregnancy are presented here, occurring within 6 months of each other; both were diagnosed only at the time of laparotomy. However, the intrauterine pregnancy was confirmed by ultrasonic investigation of the intrauterine cavity and persistently elevated serum human chorionic gonadotropin (HCG) levels after salpingectomy.

A 28-year-old white woman, gravida 9, para 2, with a history of six miscarriages, presented with an acute onset of severe, constant, sharp abdominal pain in the left lower quadrant without vaginal bleeding. The last menstrual period (LMP) was 45 days prior to admission. In the preceding 2 weeks the patient felt pregnant, with breast engorgement, nausea, vomiting, and weakness. She had no prior history of pelvic infections and had a strong family history of multiple births.

Physical examination was remarkable only for left lower quadrant abdominal tenderness without rebound. No masses were palpable nor could the uterine fundus be felt. The cervix was soft and pain was elicited on motion. No bleeding was noted. Her serum HCG was 50.5 IU. While she was in the hospital her hematocrit dropped from 37.0 to 35.4, accompanying a recurrence of abdominal pain, with passage of 50 cc of clotted blood per vaginam. Laparoscopy revealed a hemoperitoneum of 200 cc, and on laparotomy a left ampullary tubal pregnancy was present without obvious site of rupture. A left salpingectomy was performed. The uterus was enlarged to 8 weeks' gestation size and a solitary corpus luteum was noted on the left ovary. Pathologic studies confirmed the presence of a tubal pregnancy. One week postoperatively the serum HCG was 80.6 IU and ultrasonic examination verified the presence of an intrauterine pregnancy with a gestational sac consistent with 8 weeks' size. On discharge the intrauterine pregnancy was continuing uneventfully.

An 18-year-old nulliparous white woman presented with an episode of acute left lower quadrant abdominal pain without vaginal bleeding. The LMP was 55 days prior to admission. She denied a history of pelvic inflammatory disease. Physical examination revealed severe left lower quadrant tenderness with rebound tenderness. Again masses or uterine size were difficult to delineate. On admission her hematocrit dropped from 36.0 to 27.8. Exploratory laparotomy revealed 2,000 cc of clotted blood. A left salpingectomy was performed for a ruptured ampullary tubal pregnancy. Once again the uterus was found to be suspiciously large at time of laparotomy, and postoperative ultrasonic examination revealed an intrauterine gestational sac consistent with 8 week's size. In both instances the ovaries were spared to protect the corpus luteum of pregnancy. In the second case the patient later elected an abortion of the intrauterine pregnancy.

The diagnosis of combined pregnancy will not be made unless the entity is considered for all patients suspected of having an ectopic pregnancy, especially in those with the atypical presentation of having no vagi-

nal bleeding, and where the uterine size is larger than expected for an ectopic. In both cases presented, the diagnosis could have been made by preoperative ultrasonic examination. With the increased availability of diagnostic ultrasound, I suggest that all such patients receive such scans as part of their routine workup, in addition to postoperative monitoring of serum HCG levels, which is useful in those early cases where the results of the intrauterine scan can be inconclusive.

Leiomyoma of the fallopian tube: A cause of tubal pregnancy

ORRIN A. MOORE, M.D.
MARIAN WAXMAN, M.D.
CAMILLUS UDOFFIA, M.D.

Departments of Obstetrics and Gynecology and Pathology, Kings County Hospital and State University of New York, Downstate Medical Center, Brooklyn, New York

LEIOMYOMA of the oviduct causing ectopic tubal pregnancy is a rare condition in clinical practice. An example of this exceedingly rare occurrence is herein reported.

A 33-year-old woman came to the emergency room because of a lower abdominal pain associated with vaginal bleeding and syncope. She was para 1-0-0-1, her menses were always regular, and the last menstrual period occurred 48 days previously. The pain had lasted for 7 days and was accompanied by spotty vaginal bleeding for the last 4 days. The pain became severe and the bleeding heavy on the day of admission. Six hours before the patient's arrival in the emergency room, some "tissue or liverlike clots" were reportedly passed through the vagina. On physical examination, she was found well developed, in moderate distress, but alert and oriented in time, place, and person. The pulse was 100 bpm and regular and the blood pressure was 130/60 mm Hg, both in the recumbent position; in the sitting position these values changed to 140 and 90/50, respectively. The temperature was 37° C and respirations were 40 per minute. The oral mucosa and conjunctiva were pale. The abdomen was slightly distended and tender. Rebound tenderness and shifting dullness were demonstrated; the audible bowel sounds were decreased. The vagina contained dark blood. Tbe cervix was closed; it was cyanotic and tender to lateral motion. The cul-de-sac and left adnexa were bulging and tender to palpation. The uterine contour and adnexal masses could not be appreciated because of marked tenderness. The hemoglobin was 10 gm/100 ml; the hematocrit was 30 vol. %. A urine pregnancy test was positive.

Fig. 1. Leiomyoma of the proximal portion of the fallopian tube (left). Adjacent and just distal to it, a hemorrhagic area of the ruptured pregnancy is seen. Note also a separate small serosal myoma at the inferior aspect of the tube, and normal middle and distal thirds of the organ. A small hydatid cyst of Morgagni is seen close to the infundibulum.

Emergency laparotomy was performed, with the clinical diagnosis of left ruptured ectopic pregnancy. The abdominal cavity contained about 1,000 ml of mostly clotted blood. The left tube revealed a 3 by 3 cm round firm mass situated 2 cm distal from the uterine cornu. Adjacent and just distal to the mass, a ragged hemorrhagic soft area, 1 cm in size, was noted. The middle and distal thirds of the tube appeared normal. The left ovary showed a 5 cm cyst. The uterus was soft and slightly enlarged; it did not show myomas. The right ovary was represented by a palpable streak of tissue only, and the right tube appeared hypoplastic. Left salpingectomy and left ovarian cystectomy were performed.

Seen in the pathology laboratory, the fallopian tube measured 9 cm in length and 1 cm in width. The proximal part of the tube showed a 3 by 3 by 2.5 cm leiomyoma (Fig. 1); the tumor was seen partially embedded within and partially projecting outside the wall of the tube. Another small serosal myoma was attached to the tube by a slender fibrous pedicle. Just distally to the larger myoma, the wall of the tube showed the implantation site with decidua and chorionic villi. Rupture and extensive hemorrhage were evident in this area. The entire remaining fallopian tube showed normal gross and microscopic appearance, without any indication of chronic inflammatory process. The specimen of ovary proved to be a corpus luteum cyst.

Chronic salpingitis is the most frequently demonstrated cause of tubal pregnancy. Other rarer mechanical causes have been mentioned in the literature, such as tubal diverticula, extrinsic tumors, intratubal growths, and endometriosis. Leiomyomas arising in the fallopian tube are very rare; most of them are asymptomatic and without clinical significance, although rarely a torsion of a pedunculated tubal leiomyoma may occur with resulting acute abdominal symptoms. Niles and Clark,[1] in their review of 436 ectopic pregnancies, found evidence of an obstructive mechanical

phenomenon other than chronic inflammatory disease in fewer than 1% of the cases, and not a single instance of a tumor of the fallopian tube. Clearly, an ectopic pregnancy attributable to a mechanical obstruction due to a primary neoplasm of the oviduct is a rarity. Three such cases were reported in the older literature.[2] The clinical history and pathologic findings of the patient described by Sehmisch[2] were similar to those of our patient. Sehmisch's patient was a 27-year-old woman, with a history of four uncomplicated pregnancies and deliveries, operated upon because of a ruptured tubal pregnancy associated with a severe hemorrhage, caused by an obstructing leiomyoma of the tube. There was no chronic salpingitis.

The entire tube in our case was examined thoroughly, and it revealed no histologic indication of chronic inflammation, active or healed.

Asymptomatic cervicovaginal shedding of herpes simplex virus

EDEM EKWO, M.D., M.P.H.
YAU WAI WONG
MARTIN MYERS, M.D.

The University of Iowa Hospitals and Clinics, Iowa City, Iowa.

HERPES SIMPLEX VIRUS (HSV) genital infections may be asymptomatic during pregnancy and during the early postpartum period.[1] In addition, virus may be recovered from vaginal secretions of nonparturient women in the absence of lesions.[2] The recovery of 2.5 $\log_{10}$ $TCID_{50}$ HSV/ml from cervicovaginal secretions of two women 4.5 and 7 months after primary infection is reported.

Ten women seeking medical attention at the University of Iowa Student Health Center for vulvovaginitis of 3 to 10 days' duration agreed to participitate in the study. None had a history of previous venereal infection. All had a nonreactive Venereal Disease Research Laboratories (VDRL) test for syphilis. Written informed consent was obtained and the study protocol was approved by the Human Experimentation Committee of the Medical College.

Supported by a United States Public Health Service grant (AI 13627).

0002-9378/79/090102+02$00.20/0 © 1979 The C. V. Mosby Co.

The course of two of these women is reported here. The other eight women, with initial culture-proved HSV infection, were followed in an identical manner for 2 to 6 months but did not demonstrate subsequent cervicovaginal shedding of HSV.

Viral cultures were obtained on the first day of the clinic visit after a thorough pelvic examination by a gynecologist. Subsequent cervicovaginal cultures did not require a pelvic examination. Quantitative cervicovaginal cultures for HSV were obtained by use of vaginal tampons (Kotex, Comfortube, Kimberly-Clark Corp.). Each woman inserted a vaginal tampon for 5 minutes. Virus was extracted and quantitated by means of previously described methods.[3] Subsequent cultures were obtained every 10 ± 4 days when virus had been recovered on the previous culture or every 30 ± 7 days when no virus was isolated from the preceding cultures.

All virus isolates were identified as HSV type 2 by neutralization with type-specific rabbit immune sera.[4]

Over a period of 7 months, 13 cervicovaginal cultures were obtained from a 25-year-old divorced woman with no previous history of genital HSV infection. On day 6 of symptoms, consisting of burning on urination, perineal itch, and vaginal discharge, 6.0 $\log_{10}$ $TCID_{50}$ HSV/ml (Fig. 1) was recovered from the cervicovaginal secretions. The quantity of virus in the cervical secretions gradually decreased to 2.0 $\log_{10}$ $TCID_{50}$ HSV/ml by day 26. Genital symptoms except for leukorrhea had dissipated by day 13 of illness. HSV was not recovered between days 30 and 109; however, after 7 asymptomatic months, 2.5 $\log_{10}$ $TCID_{50}$ HSV/ml was recovered from the cervicovaginal secretions. A pelvic examination at this time demonstrated no vulvovaginal or cervical lesion. Transfer of the patient to another area made subsequent cultures impossible, although she reported by telephone no genital symptoms during the subsequent three weeks.

The second patient, a 28-year-old single graduate student with no previous history of HSV infection, was seen on day 4 of symptoms consisting of inguinal adenopathy, vaginal pruritus, bloody and mucous vaginal discharge, genital pain, and pain on urination. HSV, 5.5 $\log_{10}$ $TCID_{50}$ ml, was recovered from the cervicovaginal secretions. Three days later 9.5 $\log_{10}$ $TCID_{50}$ HSV/ml was recovered. Additional cultures were not possible because of discomfort until day 20, at which time 5.5 $\log_{10}$ $TCID_{50}$ HSV/ml was recovered. Symptoms persisted until day 34. No HSV was recovered from tampon cultures on days 109 and 119.

While the patient was asymptomatic, 2.5 $\log_{10}$ $TCID_{50}$ HSV/ml was recovered from the cervicovaginal secretions at 4 months. After being informed of the culture results she refused additional cultures, but she reported by telephone no genital symptoms in the subsequent weeks (Fig. 1).

Asymptomatic genital shedding of HSV has been documented in both females[1, 2] and males.[5] However, the quantity of virus shed in individual patients has not been recorded. We report the cases of two women who had shedding of 2.5 $\log_{10}$ $TCID_{50}$ HSV/ml when no evidence of infection was apparent.

In the first patient, viral shedding continued after

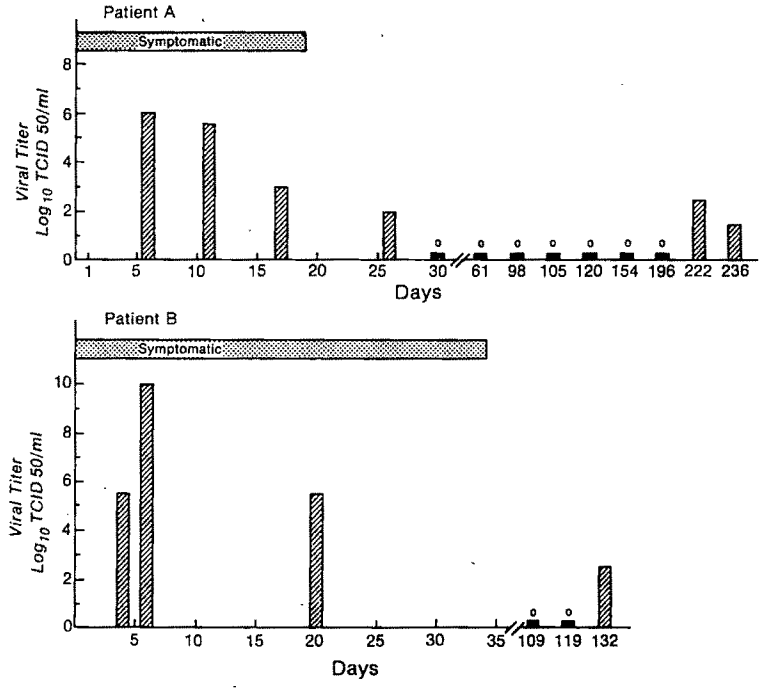

Fig. 1. Duration of symptoms and viral quantitation in two patients with genital herpes simplex virus.

genital symptoms abated. Asymptomatic cervicovaginal shedding of HSV occurred at 4.5 and 7 months after initial infections. When asymptomatic viral shedding occurred, both patients denied exposure to multiple sexual partners or to partners with genital herpetic lesions.

The titer of virus recovered during asymptomatic shedding in both patients was similar (2 $\log_{10}$ $TCID_{50}$ HSV/ml) and was less than that shed during primary infections. The mechanism of viral shedding is not clear. As all isolates were HSV 2, their courses are compatible with reactivation of latent infections or with reinfection. HSV serology was not performed on these women.

These cases demonstrate that asymptomatic genital viral shedding occurs following acute vulvovaginitis. The quantity of virus shed during primary genital infection seems to be much higher than during subsequent asymptomatic viral shedding by the same individual. Additional studies of the patterns of genital viral shedding are necessary to delineate the epidemiology of this common venereal infection, since asymptomatic shedding due to either reactivation or reinfection may be important to the spread of genital HSV.

Fetal death at term due to lightning

DILIP K. GUHA-RAY, M.B., B.S., F.R.C.S.(ENG.), M.R.C.O.G.

United States Public Health Service, Indian Medical Center, Gallup, New Mexico

LIGHTNING INJURY to a gravid woman is a rare event. Several cases, with varied fetomaternal prognoses, have been reported.[1, 2] In only one case was there immediate cessation of fetal movements and subsequent stillbirth 3 to 4 months later.[1] Another similar case is reported and the etiology, prevention, and feasibility of fetal revival in such circumstances are discussed.

The opinions expressed in this article are those of the author and do not necessarily reflect those of the United States Public Health Service or the Indian Health Service.

Reprint requests: Dr. Dilip K. Guha-Ray, Group Health Association, 2121 Pennsylvania Ave., NW, Washington, D. C. 20037.

Table I. Previously reported cases of lightning injury associated with pregnancy

Year	*Author*	*Age (yr)*	*Parity*	*Gestation (mo)*	*Loss of consciousness*	*Burn marks*	*Effect*
1833	Schieffer	?	? Multip.	8	No. Knocked down	Superficial; over left shoulder, chest, abdomen, legs	Normal delivery at term of living infant
1844	Alexander	?	?	7	No	Small superficial marks on left scapula	Mother and pregnancy remained normal next day. Further progress not reported
1891	Ebertz	28	?	7	Yes	Superficial; right shoulder, arm, breast, abdomen; deeper: thigh	Normal delivery of living infant at term
1906	Torggler	25	2	7	No. Fell off seat screaming	Left scapula, along both sides of back, around abdomen to symphysis pubis and down both legs	Immediate cessation of fetal movements. Macerated stillbirth 3-4 mo later
1959	Samsoenarjo	22	2	6+	Yes	Deep; 8-9 cm in diameter over abdomen, immediately below umbilicus	Rupture of uterus required immediate cesarean section; infant was dead but mother survived
1965	Rees	25	?	2+	Yes. Knocked down	Superficial; entry at back of neck, on right shoulder and over left mastoid region; exit burns; transversely across buttocks	Delivered normally at term
1972	Chan and Sivasamboo	29	G2 P?	Term	Yes	Irregular patch of erythema 8 cm long with wheal on right hypochondrium and paraumbilical areas	Went into labor after accident and delivered 12½ hr later normally; infant was cyanosed at birth and died 15½ hr after birth due to congestive cardiac failure
1972	Chan and Sivasamboo	19	G1 P0	Term	No. Knocked down	Irregular linear areas of erythema with accompanying wheal on lateral aspect on right shoulder, right half of ventral abdominal wall, and on medial aspect of right thigh and over left eyebrow	Went into labor after accident; delivered normally of living infant 14 hr later

A 12-year-old Navajo Indian, gravida 1, para 0, came to Gallup Indian Medical Center at term on August 19, 1977, 2 days after being struck by lightning. While standing outdoors on a cloudy day, she was struck by lightning and was unconscious for 2 to 3 minutes until she was awakened by her relatives. Upon arousal she felt no further fetal movements. Examination revealed fetal death. Spider wave pattern superficial burns were noted over the right palm, extending upward to the right axilla, and then descending along the right lateral chest wall and abdomen up to the right groin, with minimal involvement of the right lower quadrant of the abdomen. She had also a small area of superficial burn on her forehead above the right eyebrow. The burned areas healed spontaneously. Her past and family histories were unremarkable. She had no previous antenatal care. All routine antenatal investigations performed were within normal limits. Seven days later she went into labor spontaneously and was delivered of a macerated male fetus weighing 2,400 grams. The fetus and placenta grossly appeared normal. No autopsy study was performed.

Table I shows the reported cases of lightning injury in pregnant women. The first five cases were reported by Rees.[1] Labor may be induced by the shock or the passage of high-voltage current through the uterus. In advanced pregnancy, lightning can also cause severe uterine contractions, resulting in rupture of the uterus.[1] However, no maternal death was noted in the literature. Both uterus and amniotic fluid are thought to be good conductors of the electric current, which thus reaches the fetus, inducing cardiac arrest.[2]

In adults, cardiac arrest is not infrequent following lightning injury. Indefinite continuance of artificial resuscitation is advised, as frequently complete recovery is noted to occur after prolonged resuscitation. This is true because following lightning stroke the cessation of metabolism in all cells, including brain cells, is so instantaneous that onset of the degenerative process is delayed. Cardiopulmonary arrest, with fixed and di-

lated pupils, frequently noted after lightning injury, and unlike other causes, should not be taken as an indication of cerebral death. Can a fetus in utero be affected in such manner as well (after the mother had been struck by lightning)? Is it possible to resuscitate such a fetus in utero? Perhaps cardiac arrest can be produced experimentally in a fetus in utero by electric shock, followed by an attempt to resuscitate that fetus. If successful, this resuscitation procedure could be made applicable to the human fetus in utero. This could be an exciting field to study and much knowledge might be added to perinatology.

The following preventive measures are recommended when lightning threatens: if outdoors, remove all metal pieces from the head; lie flat or crouch down; move to a safer place—if possible, to a building in the immediate vicinity or to a grove of trees but never a lone tree (lightning bolts frequently strike tall lone trees). Do not remain in water if swimming or boating. If in a car, other than a convertible, stay inside. In a building, the safest place is in the basement; stay away from open doors, windows, telephone, radiators, fireplace, TV, radio, lamps, and other electric equipment; avoid washing dishes or taking showers or baths.

Spurious elevation of amniotic fluid bilirubin in acute hydramnios with fetal intestinal obstruction

RALPH J. WYNN, M.D.
RICHARD L. SCHREINER, M.D.

Department of Pediatrics, Indiana University School of Medicine, and James Whitcomb Riley Hospital for Children, Indianapolis, Indiana

LILEY[1] HAS cautioned obstetricians of a variety of potential errors in the assessment of amniotic fluid for hemolytic disease of the newborn infant. A case is presented of an elevated amniotic fluid bilirubin level, without evidence of hemolytic disease, in a woman with acute hydramnios. The infant was found to have had an in utero intestinal obstruction.

A 35-year-old woman, gravida 2, para 0, abortus 1, A-Rh negative, VDRL negative, was noted at 34 weeks' gestation to have gained only 5 kg over her prepregnancy weight; her uterine fundus was that of a 26 week gestation. An antibody screen was negative. An ultrasound at that time demonstrated a biparietal diameter compatible with a 35 week gestation fetus.

During the following week she noted increasing abdominal girth and abdominal tenderness. On examination she was noted to have gained 6 kg. Her blood pressure was unchanged and there was no proteinuria. Sonography revealed hydramnios. X-ray of the abdomen revealed no evidence of fetal skeletal anomalies. Liver, renal, and clotting function studies were normal. A 2 hour postprandial blood sugar was normal. A repeat screen for atypical antibodies was negative and a Betke-Kleihauer stain revealed no evidence of fetal-maternal transfusion.

An amniocentesis revealed yellow amniotic fluid, shake-test positive, delta O.D. 0.404 (high upper zone). Alpha fetoprotein and viral cultures were negative. A primary cesarean section was performed under general anesthesia with an estimated 3,500 cc of yellow fluid noted. The placenta weighed 750 mg without evidence of pathologic change.

A female infant, weighing 2,900 grams, at 35 to 36 weeks' gestation by examination, with Apgar scores of 1 and 4 at 1 and 5 minutes, respectively, was born. The infant was pale, with massive ascites and minimal peripheral edema. She required mechanical ventilation. The CBC revealed a hemoglobin of 8.6 gm/dl, reticulocyte count of 16.2%, RBC morphology normal, and platelet count 40,000/mm.^{3} The serum bilirubin was 1.7 mg/dl total, the total protein 4.3 gm/dl, the blood type A-Rh positive, and direct Coombs negative. A KUB demonstrated multiple loops of distended bowel with massive ascites. No intraperitoneal calcifications were noted. An abdominal paracentesis was performed for the relief of respiratory compromise and diagnosis. Approximately 120 cc of brown fluid were obtained.

At laparotomy there was meconium peritonitis with perforation, volvulus, and atresia of the distal ileum. The necrotic distal ileum and a 10 cm duplication of the small intestine were resected. Postoperatively the hemoglobin stabilized and the reticulocyte count fell to normal values. A TORCH screen and hemolytic workup were negative. She died at 7 months of age. At postmortem examination there were no other congenital anomalies.

While hydramnios may occur in up to 1 to 2% of all pregnancies, acute hydramnios is uncommon. It is often associated with uniovular twin pregnancy. When found in singleton pregnancies it is frequently associated with concealed intrapartum hemorrhage or fetal congenital anomalies. Gastrointestinal obstruction is second only to anencephaly as a fetal anomaly resulting in hydramnios.[2]

Amniocentesis has been advocated in the management and diagnosis of acute hydramnios. Liley[1] noted that the 450 μm absorption peak of amniotic fluid may be enlarged misleadingly by contamination with the heavily pigmented serum of an affected fetus, by the presence of meconium, or by the regurgitation of bile in the case of obstruction of the alimentary tract distal to the papilla of Vater.

Intestinal atresia has been diagnosed in utero by the

Reprint requests: Ralph J. Wynn, M.D., Department of Pediatrics, Children's Hospital of Buffalo, 219 Bryant St., Buffalo, New York 14222.

use of amniofetography. The injection of iodide-containing dyes into the amniotic fluid may not be without risk to fetal thyroid function.[3] A method for the determination of bile acid concentration in the amniotic fluid has been described.[4] The measurement of these bile acids may be a useful diagnostic procedure in the evaluation of patients with hydramnios and would permit the prenatal diagnosis of intestinal obstruction distal to the papilla of Vater.

In the case presented, both the obstetrician and the pediatrician were led to believe that the high elevation of the spectral absorption curve was due to a hemolytic process. The subsequent finding of intra-abdominal hemorrhage, a negative hemolytic evaluation, and the lack of a rapid rise in serum bilirubin are all factors which negate the diagnosis of a hemolytic disorder. The elevated reticulocyte count and low hemoglobin, secondary to intra-abdominal hemorrhage, remained normal after postoperative blood replacement. These findings are in agreement with the conclusion of an acute intra-abdominal catastrophe in utero resulting in acute hydramnios with regurgitation of bile into the amniotic fluid.

Pediatric and Adolescent Gynecology

The Department of Obstetrics and Gynecology and The Page and William Black Post-Graduate School of Medicine of the Mount Sinai School of Medicine (City University of New York) announce a postgraduate course, "Pediatric and Adolescent Gynecology, under the Direction of Albert Altchek, M.D., with guest faculty and faculty of the Mount Sinai School of Medicine, to be presented June 7 and 8, 1979, 9:00 AM to 5:00 PM (two sessions).

Apply to: Director, The Page and William Black Post-Graduate School of Medicine, Mount Sinai School of Medicine, One Gustave L. Levy Place, New York, New York 10029. Telephone: (212) 650-6737.

IUD and Biodegradable Delivery Systems

An international symposium, "IUD and Biodegradable Delivery Systems" will be held in Amsterdam, Holland, June 28-30, 1979. Program Directors are W. van Os, Haarlem, Holland, and E. S. E. Hafez, Detroit, Michigan. For information contact: Symposium Office, Miss K. Spanjaard, P. O. Box 20, 5340 Oss, Holland, Telex: 50959.

Seventh Annual Breastfeeding Seminar for Physicians

The Seventh Annual Breastfeeding Seminar for Physicians, sponsored by La Leche League International, will be held on July 6, 1979, at The Atlanta Hilton, Atlanta, Georgia, from 9:00 A.M. to 4:30 P.M.

For further information contact: Carol Kolar, R.N., Coordinator, Continuing Medical Education, La Leche League International, 9616 Minneapolis Ave., Franklin Park, Illinois 60131.

Bioethics and Public Policy

The Institute of Society, Ethics and the Life Sciences will sponsor a workshop this summer on "Bioethics and Public Policy," which will be held at the University of Colorado in Boulder, Colorado, from July 15 through 22, 1979.

For information contact: The Hastings Center, 360 Broadway, Hastings-on-Hudson, New York, 10706. Telephone: (914) 478-0500.

BELLERGAL-S™ TABLETS

Composition: Each Bellergal-S Tablet contains: phenobarbital, USP, central sedative (Warning: May be habit forming), 40.0 mg; Gynergen (ergotamine tartrate, USP) sympathetic inhibitor, 0.6 mg; Bellafoline (levorotatory alkaloids of belladonna, as malates) parasympathetic inhibitor, 0.2 mg.

Properties and Therapeutics: Based on the concept that functional disorders frequently involve hyperactivity of both the sympathetic and parasympathetic nervous systems, the ingredients in Bellergal are combined to provide a balanced preparation designed to correct imbalance of the autonomic nervous system. The integrated action of Bellergal is effected through the combined administration of ergotamine and the levorotatory alkaloids of belladonna, specific inhibitors of the sympathetic and parasympathetic respectively, reinforced by the synergistic action of phenobarbital in dampening the cortical centers.

Indications: Bellergal is employed in the management of disorders characterized by nervous tension and exaggerated autonomic response:

Menopausal disorders with hot flashes, sweats, restlessness and insomnia.

Cardiovascular disorders with palpitation, tachycardia, chest oppression and vasomotor disturbances.

Gastrointestinal disorders with hypermotility, hypersecretion, "nervous stomach," and alternately diarrhea and constipation.

Genitourinary—uterine cramps, etc.

Premenstrual tension.

Interval treatment of *recurrent, throbbing headache.*

Contraindications: Peripheral vascular disease, coronary heart disease, hypertension, impaired hepatic or renal function, sepsis, third trimester of pregnancy and glaucoma. Hypersensitivity to any of the components.

Precautions: Even though the ergotamine tartrate content of this product is extremely low and untoward effects have been rare and insignificant, caution should be exercised if large or prolonged dosage is contemplated, and physicians should be alert to possible peripheral vascular complications in patients highly sensitive to ergot. Due to presence of a barbiturate, may be habit forming.

Side Effects: Blurred vision, dry mouth, flushing, drowsiness occur rarely.

Dosage: Bellergal-S Tablets: One in the morning and one in the evening.

How Supplied: Bellergal-S Tablets (compressed, scored tablets of tricolored pattern: dark green, orange and light lemon yellow) in bottles of 100.

Dorsey LABORATORIES
Division of Sandoz, Inc.
LINCOLN, NEBRASKA 68501

NONHORMONAL therapy for menopausal vasomotor instability is receiving renewed attention.

BELLERGAL-S™

TABLETS

Each Bellergal-S Tablet contains: phenobarbital, USP, central sedative (Warning: May be habit forming), 40.0 mg; Gynergen® (ergotamine tartrate, USP) sympathetic inhibitor, 0.6 mg; Bellafoline® (levorotatory alkaloids of belladonna, as malates) parasympathetic inhibitor, 0.2 mg.

Long clinical experience has established the effectiveness of Bellergal-S Tablets in managing menopausal disorders characterized by exaggerated autonomic response—hot flashes, sweats, restlessness, and insomnia.

Because Bellergal-S reduces autonomic nervous system activity, symptoms of vasomotor instability are eliminated or significantly reduced. *Bellergal-S does not contain estrogen in any form.* That's one reason why it is receiving renewed attention from physicians who wish to avoid the potential complications of estrogen therapy in vasomotor instability.

So when estrogen therapy is undesirable... prescribe Bellergal-S Tablets.

Please see prescribing information on an adjoining page.

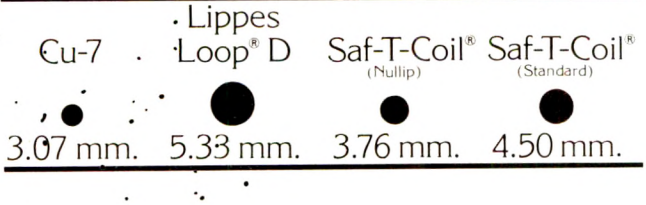
Why the choice is Cu-7®

intrauterine copper contraceptive.



1. She wants nonhormonal contraception.
2. She wants to space her family.
3. She smokes.
4. She has passed the "Pill" years.

Freedom—intrauterine contraception is the most convenient of all contraceptive methods.

Comfort—smallest inserter diameter of all IUDs. This means minimal discomfort during insertion.

Security—high efficacy and relatively low incidence of expulsion and medical removal.

(Rates—based on labeling claims—expressed as events per 100 women through 12 months of use for parous women)[1]	Cu-7[1]	Lippes Loop D[2]	Saf-T-Coil[2]
Pregnancy	1.9	2.7	2.4
Expulsion	5.7	12.7	18.3
Medical Removal	10.9	15.2	15.6

These rates are derived from separate studies conducted by different investigators in several population groups. Different rates have been reported from other clinical trials.

References: 1. Data on file at Searle Laboratories. 2. Physicians' Desk Reference, Medical Economics Company, Oradell, N.J., 1978, pp. 1216, 1521.

Intrauterine contraception is not appropriate for all women. Please see complete product information prior to use. A brief summary of product information appears on the next page

Description: The plastic component of the Cu-7 is composed of pharmaceutical grade polypropylene homopolymer with barium sulfate added to render it radiopaque. Its shape approximates the number 7. It is substantially smaller than previously available intrauterine devices; the vertical dimension measures 36 mm. and the horizontal, 26 mm.

Coiled around the vertical limb is a pure, virgin electrolytic copper wire providing approximately 200mm^2 of exposed copper surface area. A retrieval thread is fastened to the free end of the vertical limb of the Cu-7.

The Cu-7 is supplied with a simple tubular polypropylene inserter. All components are sterile.

Mode of Action: Available data indicate that the contraceptive effectiveness of the Cu-7 is enhanced by a minute quantity of copper released continuously from the coiled copper into the uterine cavity.

The exact mechanism by which metallic copper enhances the contraceptive effect of an IUD has not been conclusively demonstrated. Various hypotheses have been advanced, the most common being that copper placed in the uterus interferes with enzymatic or other processes that regulate blastocyst implantation.

Animal studies suggest that copper may play an additional role by reduction of sperm transport within the uterine environment.

Indication and Usage: The Cu-7 is indicated for contraception.

Contraindications: The Cu-7 should not be inserted when any of the following conditions exist: pregnancy or suspicion of pregnancy; abnormalities of the uterus resulting in distortion of the uterine cavity; acute pelvic inflammatory disease or a history of repeated pelvic inflammatory disease; postpartum endometritis or infected abortion in the past three months; known or suspected uterine or cervical disease such as hyperplasia or carcinoma including unresolved, abnormal "Pap" smear; vaginal bleeding of unknown etiology; untreated acute cervicitis until infection is controlled; diagnosed Wilson's disease; known or suspected allergy to copper; previous ectopic pregnancy, and significant anemia.

Warnings

1. Pregnancy: (a) Long-term effects. The long-term effects on the offspring of the presence of copper in the uterus when pregnancy occurs with the Cu-7 are unknown.

(b) Septic abortion. Reports have indicated an increased incidence of septic abortion associated in some instances with septicemia, septic shock and death in patients becoming pregnant with an IUD in place. Most of these reports have been associated with the mid-trimester of pregnancy. In some cases, the initial symptoms have been insidious and not easily recognized. If pregnancy should occur with a Cu-7 in situ, the Cu-7 should be removed if the thread is visible or, if removal proves to be or would be difficult, interruption of the pregnancy should be considered and offered to the patient as an option, bearing in mind that the risks associated with an elective abortion increase with gestational age.

(c) Continuation of pregnancy. If the patient chooses to continue the pregnancy and the Cu-7 remains in situ, she must be warned of the increased risk of spontaneous abortion and the increased risk of sepsis, including death. The patient must be closely observed and she must be advised to report immediately all abnormal symptoms, such as flu-like syndrome, fever, abdominal cramping and pain, bleeding, or vaginal discharge, because generalized symptoms of septicemia may be insidious.

2. Ectopic pregnancy: (a) A pregnancy which occurs with an IUD in situ is more likely to be ectopic than a pregnancy occurring without an IUD. Therefore, patients who become pregnant while using a Cu-7 should be carefully evaluated for the possibility of an ectopic pregnancy.

(b) Special attention should be directed to patients with delayed menses, slight metrorrhagia and/or unilateral pelvic pain, and to those patients who wish to interrupt a pregnancy occurring in the presence of a Cu-7, to determine whether ectopic pregnancy has occurred.

3. Pelvic infection. An increased risk of pelvic inflammatory disease associated with the use of IUDs has been reported. While unconfirmed, this risk appears to be greatest for young women who are nulliparous and/or who have a multiplicity of sexual partners. Salpingitis can result in tubal damage and occlusion, thereby threatening future fertility. Therefore, it is recommended that patients be taught to look for symptoms of pelvic inflammatory disease. The decision to use an IUD in a particular case must be made by the physician and patient with the consideration of a possible deleterious effect on future fertility.

Pelvic infection may occur with a Cu-7 in situ and at times result in the development of tubo-ovarian abscesses or general peritonitis. The symptoms of pelvic infection include: new development of menstrual disorders (prolonged or heavy bleeding), abnormal vaginal discharge, abdominal or pelvic pain, dyspareunia, fever. The symptoms are especially significant if they occur following the first two or three cycles after insertion. Appropriate aerobic and anaerobic bacteriologic studies should be done and antibiotic therapy initiated promptly. If the infection does not show marked clinical improvement within 24 to 48 hours, the Cu-7 should be removed and the continuing treatment reassessed on the basis of the results of culture and sensitivity tests.

4. Embedment. Partial penetration or lodging of the Cu-7 in the endometrium or myometrium can result in a difficult removal. This may occur more frequently in smaller uteri. (See removal instructions.)

5. Perforation. Partial or total perforation of the uterine wall or cervix may occur with the use of the Cu-7, usually during insertions into patients sooner than two months after abortion or delivery or in uterine cavities too small for the Cu-7. The possibility of perforation must be kept in mind during insertion and at the time of any subsequent examination. If perforation occurs, laparotomy or laparoscopy should be performed as soon as medically feasible and the Cu-7 removed. Abdominal adhesions, intestinal penetration, intestinal obstruction, and local inflammatory reaction with abscess formation and erosion of adjacent viscera may result if the Cu-7 is left in the peritoneal cavity.

6. Medical diathermy. The use of medical diathermy (short-wave and microwave) in a patient with a metal-containing IUD may cause heat injury to the surrounding tissue. Therefore, medical diathermy to the abdominal and sacral areas should not be used on patients using a Cu-7.

7. Effects of copper. Additional amounts of copper available to the body from the Cu-7 may precipitate symptoms in women with undiagnosed Wilson's disease. The incidence of Wilson's disease is 1 in 200,000.

Precautions

1. Patient counseling. Prior to the insertion the physician, nurse, or other trained health professional must provide the patient with the Patient Brochure. The patient should be given the opportunity to read the brochure and discuss fully any questions she may have concerning the Cu-7 as well as other methods of contraception.

2. Patient evaluation and clinical considerations: a) A complete medical history should be obtained to determine conditions that might influence the selection of an IUD. A physical examination should include a pelvic examination, "Pap" smear, gonorrhea culture and, if indicated, appropriate tests for other forms of venereal disease. The physician should determine that the patient is not pregnant.

(b) The uterus should be carefully sounded prior to the insertion to determine the degree of patency of the endocervical canal and the internal os, and the direction and depth of the uterine cavity. Exercise care to avoid perforation with the sound. DO NOT USE THE Cu-7 INSERTION INSTRUMENT AS A SOUND. In occasional cases, severe cervical stenosis may be encountered. Do not use excessive force to overcome this resistance.

(c) The uterus usually sounds to a depth of 6 to 8 cm. Insertion of a Cu-7 into a uterine cavity measuring less than 6.5 cm. by sounding may increase the incidence of pain, bleeding, partial or complete expulsion, perforation, and possibly pregnancy.

(d) To reduce the possibility of insertion in the presence of an existing undetermined pregnancy, the optimal time for insertion is the latter part of the menstrual flow or one or two days thereafter. The Cu-7 should not be inserted post partum or post abortion until involution of the uterus is complete. The incidence of perforation and expulsion is greater if involution is not complete.

It is, however, necessary to place the Cu-7 as high as possible within the uterine cavity to help avoid partial or complete expulsion that could result in pregnancy.

Since the Cu-7 represents a different design in intrauterine contraception, physicians are cautioned that it is imperative for them to become thoroughly familiar with the instructions for use before attempting placement of the Cu-7.

(e) IUDs should be used with caution in those patients who have an anemia or a history of menorrhagia or hypermenorrhea. Patients experiencing menorrhagia and/or metrorrhagia following IUD insertion may be at risk for the development of hypochromic microcytic anemia. Also, IUDs should be used with caution in patients receiving anticoagulants or having a coagulopathy.

(f) Syncope, bradycardia or other neurovascular episodes may occur during insertion or removal of IUDs, especially in patients with a previous disposition to these conditions.

(g) Patients with valvular or congenital heart disease are more prone to develop subacute bacterial endocarditis than patients who do not have valvular or congenital heart disease. Use of an IUD in these patients may represent a potential source of septic emboli.

(h) Use of an IUD in those patients with acute cervicitis should be postponed until proper treatment has cleared up the infection.

(i) Since the Cu-7 may be partially or completely expelled, patients should be reexamined and evaluated shortly after the first postinsertion menses, but definitely within three months after insertion. Thereafter annual examination with appropriate medical and laboratory evaluation should be carried out. The Cu-7 should be replaced every three years.

(j) The patient should be told that some bleeding or cramps may occur during the first few weeks after insertion, but if these symptoms continue or are severe she should report them to her physician. She should be instructed on how to check after each menstrual period to make certain that the thread still protrudes from the cervix and cautioned that there is no contraceptive protection if the Cu-7 has been expelled. She should also be cautioned not to dislodge the Cu-7 by pulling on the thread. If a partial expulsion occurs, removal is indicated and a new Cu-7 may be inserted. The patient should be told to return within three years for removal of the Cu-7 and for replacement if desired.

(k) A copper-induced urticarial allergic skin reaction may develop in women using a copper-containing IUD. If symptoms of such an allergic response occur, the patient should be instructed to tell the consulting physician that a copper-containing device is being used.

(l) The Cu-7 should be removed for the following medical reasons: menorrhagia and/or metrorrhagia producing significant anemia; uncontrolled pelvic infection; intractable pain often aggravated by intercourse, dyspareunia; pregnancy, if the thread is visible; endometrial or cervical malignancy; uterine or cervical perforation; or any indication of partial expulsion.

(m) If the retrieval thread cannot be visualized it may have retracted into the uterus or have been broken off, or the Cu-7 may have been expelled. Localization usually may be made by feeling with a probe; if not, x-ray or sonography can be used. When the physician elects to recover a Cu-7 with the thread not visible, the removal instructions should be considered.

(n) If any patient with a Cu-7 suddenly develops overt clinical hepatitis or abnormal liver function tests, appropriate diagnostic procedures should be initiated.

Adverse Reactions: Perforations of uterus and cervix have occurred. Perforation into the abdomen has been followed by abdominal adhesions, intestinal penetration, intestinal obstruction, local inflammatory reaction with abscess formation and erosion of adjacent viscera. Pregnancy has occurred with the Cu-7 in situ and when the Cu-7 has been partially or completely expelled.

The incidence of spontaneous abortion, when conception occurs with intrauterine devices in situ, appears to be increased over that in unprotected women. Insertion cramping, usually of no more than a few seconds duration, may occur; however, some women may experience residual cramping for several hours or even days. Intermenstrual spotting or bleeding or prolonged or increased menstrual flow may occur.

Pelvic infection including salpingitis with tubal damage or occlusion has been reported. This may result in future infertility. Complete or partial expulsion of the Cu-7 may sometimes occur, particularly in those patients with uteri measuring less than 6.5 cm. by sounding. Urticarial allergic skin reaction may occur. The following complaints have also been reported with IUDs although their relation to the Cu-7 has not been established: amenorrhea or delayed menses, backaches, cervical erosion, cystic masses in the pelvis, vaginitis, leg pain or soreness, weight loss or gain, nervousness, dyspareunia, cystitis, endometritis, septic abortion, septicemia, leukorrhea, ectopic pregnancy, difficult removal, uterine embedment, anemia, pain, neurovascular episodes including bradycardia and syncope secondary to insertion, dysmenorrhea, and fragmentation of the IUD.

Directions for Use: The Cu-7 is to be placed within the uterine cavity. See the Procedure for Insertion for two insertion techniques.

The small diameter of the Cu-7 facilitates easy insertion in nulligravidous and nulliparous, as well as parous women. The optimal time of insertion is during the latter part of the menstrual flow or one or two days thereafter. The cervical canal is relatively more patent at this time, and there is little chance that the patient may be pregnant.

Present information indicates that efficacy is retained for 36 months. There is no evidence that contraceptive efficacy decreases with time up to three years of use, but until adequate data indicating a longer effective life become available, the Cu-7 must be removed within 36 months from the date of insertion and a new one inserted if desired. If partial expulsion occurs, removal is indicated, and a new Cu-7 may be inserted. Removal of the Cu-7 may also be indicated in the event of heavy or persistent bleeding.

The physician should become thoroughly familiar with the instructions for use before attempting insertion or removal of the Cu-7.

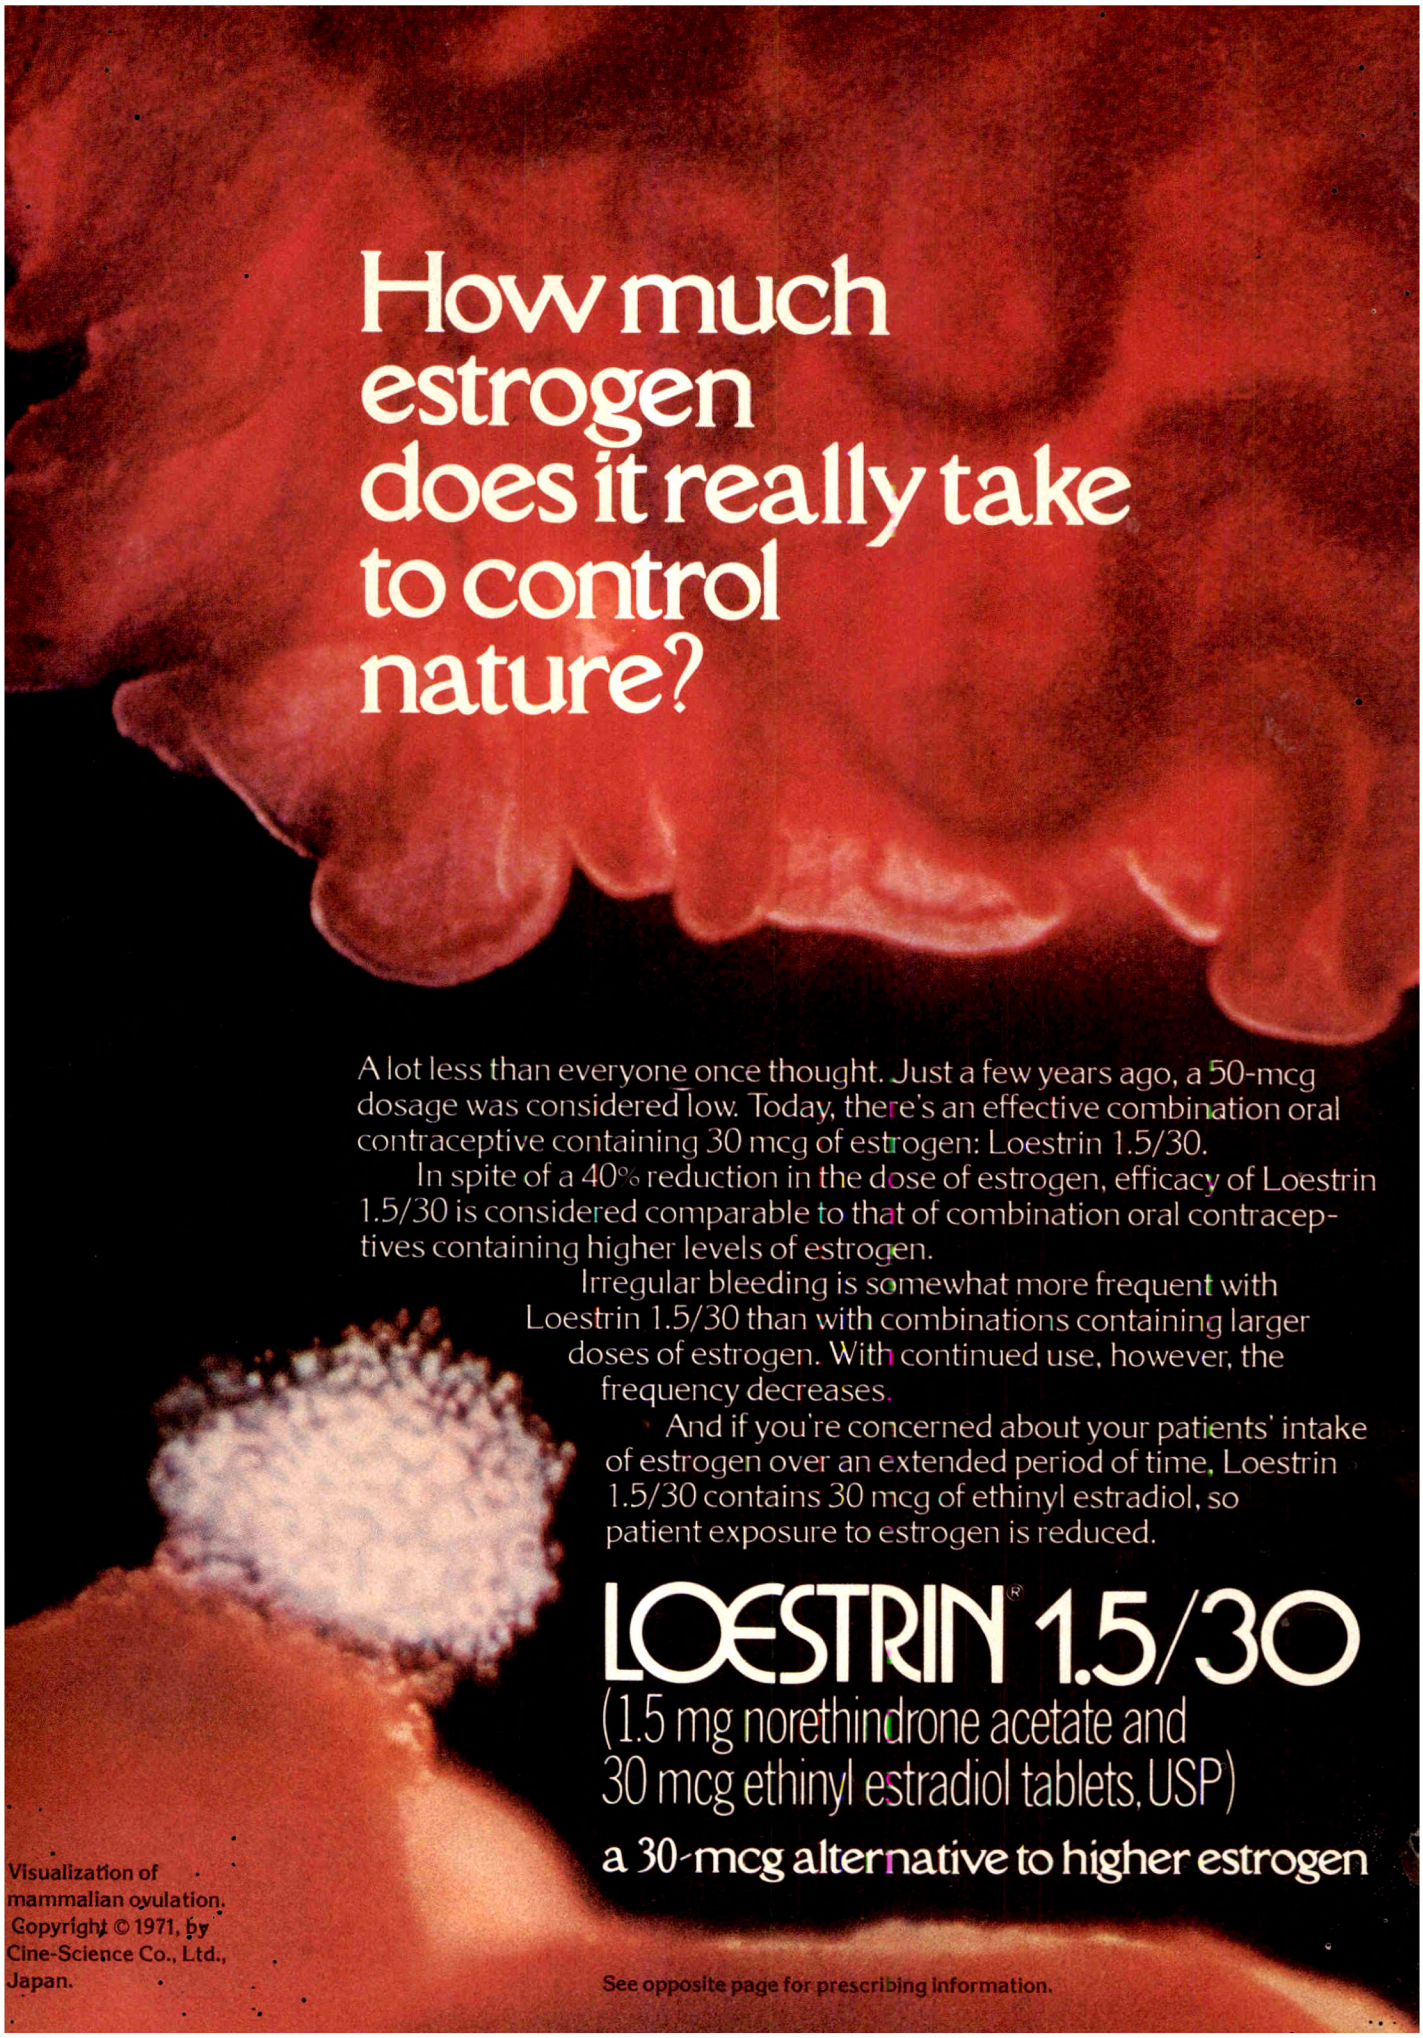
Clinical Efficacy: In clinical trials of the Cu-7 conducted by Searle Laboratories, use effectiveness was determined as follows for parous and nulliparous women, as tabulated by the life table method. (Rates are expressed as cumulative events per 100 women through 12, 24, and 36 months of use.)

This experience encompasses 387,131 woman-months of use, including 12 months for 11,517 women, 24 months for 7,895, and 36 months for 3,661.

	12 Months		24 Months		36 Months	
	Parous	Nulliparous	Parous	Nulliparous	Parous	Nulliparous
Pregnancy	1.9	1.7	2.9	2.6	3.4	3.4

How Supplied

Available in cartons of 6, 30 and 100 sterile units (Cu-7 with an inserter) and sufficient patient leaflets and identification cards.



Please see complete product labeling for additional information, including insertion and removal instructions.

Cu-7® intrauterine copper contraceptive

—the leading IUD

8B4

How much estrogen does it really take to control nature?
A lot less than everyone once thought. Just a few years ago, a 50-mcg dosage was considered low. Today, there's an effective combination oral contraceptive containing 30 mcg of estrogen: Loestrin 1.5/30.
In spite of a 40% reduction in the dose of estrogen, efficacy of Loestrin 1.5/30 is considered comparable to that of combination oral contraceptives containing higher levels of estrogen.
Irregular bleeding is somewhat more frequent with Loestrin 1.5/30 than with combinations containing larger doses of estrogen. With continued use, however, the frequency decreases.
And if you're concerned about your patients' intake of estrogen over an extended period of time, Loestrin 1.5/30 contains 30 mcg of ethinyl estradiol, so patient exposure to estrogen is reduced.
LOESTRIN® 1.5/30
(1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP)
a 30-mcg alternative to higher estrogen
Visualization of mammalian ovulation. Copyright © 1971, by Cine-Science Co., Ltd., Japan.
See opposite page for prescribing information.

Brief Summary of Prescribing Information
LOESTRIN® 1.5/30
(1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP) See section under Special Notes on Administration and How Supplied.

DESCRIPTION
Loestrin 1.5/30 Products are progestogen-estrogen combinations.

INDICATION AND USAGE
Loestrin 1.5/30 Products are indicated for the prevention of pregnancy in women who elect to use oral contraceptives.

In clinical trials with Loestrin 1.5/30 involving 17,139 therapy cycles, there was a pregnancy rate of 0.49 per 100 woman years.

Dose-related risk of thromboembolism from oral contraceptives: Studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. It is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance.

CONTRAINDICATIONS
1. Thrombophlebitis or thromboembolic disorders
2. A past history of deep-vein thrombophlebitis or thromboembolic disorders
3. Cerebral vascular or coronary artery disease
4. Known or suspected carcinoma of the breast
5. Known or suspected estrogen-dependent neoplasia
6. Undiagnosed abnormal genital bleeding
7. Known or suspected pregnancy (See No. 5 under WARNINGS.)

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, and hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well-established. Studies have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic.

Cerebrovascular disorders: In a collaborative study in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers, and the risk of thrombotic stroke was 4.0 to 9.5 times greater.

Myocardial infarction: An increased risk of myocardial infarction associated with oral contraceptives has been reported confirming a previously suspected association. These studies found that the greater the number of underlying risk factors (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) for coronary artery disease, the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor.

It has been estimated that users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are smokers have about a fivefold increased risk of fatal infarction compared to users who do not smoke, but about a tenfold to twelvefold increased risk compared to nonusers who do not smoke. The amount of smoking is also an important factor.

Risk of dose: In an analysis of data, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; however, the quantity of estrogen may not be the sole factor involved.

Estimate of excess mortality from circulatory diseases: The risk of diseases of the circulatory system is concentrated in older women, in those with a long duration of use, and in cigarette smokers.

A study of available data from a variety of sources concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke.

The risk of thromboembolic and thrombotic diseases associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders. Should any occur or be suspected, the drug should be discontinued immediately.

A fourfold to sixfold increased risk of postsurgery thromboembolic complications has been reported in users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

2. *Ocular lesions:* Neuro-ocular lesions, such as optic neuritis or retinal thrombosis, have been associated with the use of oral contraceptives. Discontinue the oral contracept ve if there is unexplained sudden or gradual, partial, or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions.

3. *Carcinoma:* Long-term continuous administration of estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver.

In humans, an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women has been reported. However, there is no evidence suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives.

Studies found no evidence of increase in breast cancer in women taking oral contraceptives; however, an excess risk in users with documented benign breast disease was reported.

There is no confirmed evidence of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of users is, nevertheless, essential. In cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer, or who have breast nodules, fibrocystic disease, or abnormal mammograms, should be monitored with particular care.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with oral contraceptives. Because hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage, they should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock.

A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Usage in or Immediately Preceding Pregnancy; Birth Defects in Offspring, and Malignancy in Female Offspring:* During early pregnancy, female sex hormones may seriously damage the offspring.

An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of oral contraceptives in pregnancy.

There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives.

Pregnancy should be ruled out before continuing an oral contraceptive in any patient who has missed two consecutive menstrual periods. If the patient has not adhered to the schedule, the possibility of pregnancy should be considered at the time of the first missed period, and oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed.

Women who discontinue oral contraceptives with the intent of becoming pregnant should use an alternate form of contraception for a period of time before attempting to conceive.

Administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives.

7. *Carbohydrate and Lipid Metabolic Effects:* Because decreased glucose tolerance has been observed in a significant percentage of patients, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives.

An increase in triglycerides and total phospholipids has been observed.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving oral contraceptives. The prevalence in users increases with longer exposure. Age is also strongly correlated with development of hypertension. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure.

9. *Headache:* Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, nonfunctional causes should be borne in mind. In undiagnosed abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy.

Women with a past history of oligomenorrhea or secondary amenorrhea, or young women without regular cycles should be advised that they may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast Feeding:* Oral contraceptives may interfere with lactation. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs.

PRECAUTIONS
1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another examination.
2. Preexisting uterine leiomyomata may increase in size.
3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.
4. Oral contraceptives may cause fluid retention and should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated.
5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice. If jaundice develops, the medication should be discontinued.
6. Steroid hormones may be poorly metabolized and should be administered with caution in patients with impaired liver function.
7. Users may have disturbances in normal tryptophan metabolism, which may result in a relative pyridoxine deficiency.
8. Serum folate levels may be depressed.
9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted.
10. Certain endocrine and liver function tests and blood components may be affected. (a) Increased sulfobromophthalein retention. (b) Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. (c) Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone. (d) Decreased pregnanediol excretion. (e) Reduced response to metyrapone test.

Drug interactions: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin and an association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin.

ADVERSE REACTIONS
An increased risk of the following serious adverse reactions has been associated with oral contraceptives.

Thrombophlebitis; Pulmonary embolism; Coronary thrombosis; Cerebral thrombosis; Cerebral hemorrhage; Hypertension; Gallbladder disease; Benign hepatomas; Congenital anomalies.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis, Neuro-ocular lesions, eg, retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms; breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma; breast changes; change in weight; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately post partum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature; intolerance to contact lenses.

The following adverse reactions have been reported and the association has been neither confirmed nor refuted.

Premenstrual-like syndrome; cataracts; changes in libido; chorea; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis; porphyria.

Special Notes on Administration
Loestrin 21 1.5/30 (1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP)—Menstruation usually begins two or three days, but may begin as late as the fourth or fifth day, after discontinuing medication.

Loestrin Fe 1.5/30—Menstruation usually begins two or three days, but may begin as late as the fourth or fifth day, after the brown ferrous fumarate tablets have been started.

Because of the relatively low estrogenic content, Loestrin 1.5/30 is not a good cyclic regulator. There are patients whose inherent hormone balance will require larger amounts of estrogen than that contained in Loestrin 1.5/30 to achieve cyclic regularity. These patients experience altered bleeding patterns, which do not conform to treatment schedules.

The physician should be alert to the fact that the irregular bleeding patterns could mask bleeding from organic cause, and appropriate diagnostic measures should be taken if the bleeding persists or continues after changing to a higher estrogen-content product.

After several months, bleeding may be reduced to a virtual absence; reduced flow may be a result of medication and not indicative of pregnancy.

HOW SUPPLIED
Loestrin Fe 1.5/30 is available in compacts each containing 21 green tablets and 7 brown tablets. Each green tablet contains 1.5 mg of norethindrone acetate and 30 mcg of ethinyl estradiol. Each brown tablet contains 75 mg of ferrous fumarate. Available in packages of five compacts and packages of five refills.

Loestrin 21 1.5/30 is available in compacts each containing 21 tablets. Each green tablet contains 1.5 mg of norethindrone acetate and 30 mcg of ethinyl estradiol. Available in packages of five compacts and packages of five refills.

95% of American women of child-bearing age have inadequate iron intake.[1] About 50% have laboratory evidence of iron depletion.[2]

Just any iron may not solve the problem.

Any iron may cause GI irritation and constipation. To avoid patient resistance—especially during pregnancy when iron requirements are greater than ever—be specific. Recommend FERRO-SEQUELS.® Its delayed release avoids absorption of iron in the stomach. Instead, most of the iron is released gradually in the duodenum for optimum absorption and minimum irritation. And FERRO-SEQUELS contains a stool softener to help prevent constipation.

An iron that encourages compliance is an iron worth being specific about.

FERRO·SEQUELS®

Sustained Release Iron Capsules

Each capsule contains:	
Ferrous Fumarate (equivalent to approx. 50 mg. of elemental iron)	150 mg.
Dioctyl Sodium Sulfosuccinate	100 mg.

It's revolutionized obstetrics.

Let us show you why.

Real-time ultrasound provides answers to questions in pregnancy that previously went unanswered until delivery. The ADR Real-Time Scanner is being used daily by physicians in more than 500 hospitals and private practices to confirm diagnoses, detect problems, date gestation, assess fetal status and much more. Because ADR has far more clinical and technological experience than anyone else in our field, you can be assured of proven reliability, the latest advances in image quality and convenience, and a professional training program.

But you don't have to believe us—we want to *show* you. Return the coupon today—or call toll-free (800) 528-1447—to request a video tape presentation or a clinical demonstration in your office. And ask us for the names of ADR customers in your area—they'll tell you how the ADR Scanner has revolutionized the practice of obstetrics for them.

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

> *"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."*

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

By Lois DeBakey, Ph.D. In collaboration with: Paul F. Cranefield, M.D., Ph.D.; Ayodhya P. Gupta, M.D.; Franz J. Ingelfinger, M.D.; Robert J. Levine, M.D.; Robert H. Moser, M.D.; J. Roger Porter, Ph.D.; and F. Peter Woodford, Ph.D. August, 1976. 128 pages, 6″ × 9″. Price, $12.50.

Feosol®. Because stomachs aren't made of iron.

Feosol Spansule Capsules provide ferrous sulfate—iron in its most efficient (bivalent) form. Without extraneous minerals and vitamins. The iron is divided among coated pellets that disperse in the upper GI tract. The result is minimal stomach distress, hence fewer skipped doses. And studies* show that iron from Spansule Capsules is absorbed as completely as iron from solution.

Feosol. The brand of iron therapy most often recommended by physicians for iron deficiency and iron-deficiency anemia. Ask your Smith Kline & French Representative for samples.

Controlled-release pellets are designed to disperse the iron in the upper GI tract to minimize stomach distress.

ANNOUNCEMENT

21ST ANNUAL
EMIL NOVAK MEMORIAL

Course in Gynecological Pathology, Cytogenetics and Endocrinology, In Conjunction With Intrauterine Development and Fetal Management.

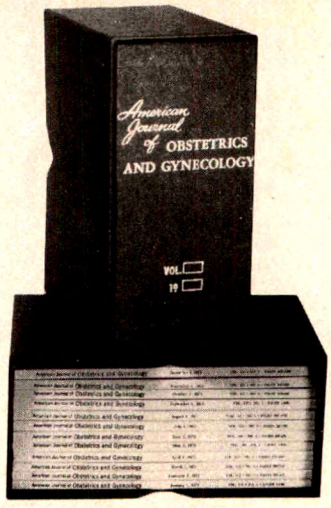
GYNECOLOGICAL PATHOLOGY (2½ days) October 18-20, 1979—Drs. R. F. Mattingly, E. R. Novak, and J. Donald Woodruff.

CYTOGENETICS AND ENDOCRINOLOGY (2½ days) October 22-24, 1979 —Drs. T. Baramki, Georgeanna S. Jones and Howard W. Jones.

INTRAUTERINE DEVELOPMENT AND FETAL MANAGEMENT (2½ days) October 24-26, 1979—Drs. J. W. C. Johnson, Asa E. Seeds and Norman F. Gant, Jr.

Applicants may sign up for any of the courses ($250.00) or may elect all three ($700.00).

They represent a complete and updated review of the above topics by well-known teachers, and will also act as an excellent refresher course for American Board applicants. It is appropriate for an Ob. Gyn. clinician desiring a rapid resume of the most recent concepts.



Each 2½ day course is complete in itself, but may be correlated with others. A collection of over fifty 35 mm. slides will be available on registration.

All checks should be made out to the Johns Hopkins University. The complete program will be available in May, but the program is limited to 150 to provide for informal discussion and question-answer periods. No application accepted after September 1st, or unless accompanied by check made out to the Johns Hopkins University.

FACULTY POSITIONS

There are currently openings for full-time faculty in Obstetrics and Gynecology who have Board certification or eligibility. Teaching, research and patient care interests important. Special training and expertise in maternal and fetal medicine, reproductive endocrinology, gynecologic oncology or ambulatory care is desired. Academic rank and salary are dependent on qualifications. If interested, please send curriculum vitae and bibliography to:

William N. Spellacy, M.D.
Professor and Head
Department of Obstetrics & Gynecology
Abraham Lincoln School of Medicine
University of Illinois Medical Center
840 South Wood Street
Chicago, Illinois 60612

(Affirmative Action/Equal Opportunity Employer)

DIRECTOR OBSTETRICS AND GYNECOLOGY

Full time, Waterbury Hospital. Yale University Affiliated 500 bed teaching hospital. To direct training of Yale Obs/Gyn residents and medical students. To help ensure high quality of patient care. To coordinate continuing education for physicians in practice. Hospital also has residency programs in Medicine, Surgery, Pediatrics, Radiology, Urology and Orthopedics with relationships with Yale or University of Connecticut. Medical students from Yale, U. Connecticut, Dartmouth, other schools receive training at W.H. Salary competitive, excellent fringe benefits, referral private practice permitted. Yale Clinical Faculty Appointment. Prerequisites: Academically oriented, board certified skilled clinician and teacher with administrative experience and/or ability. Three or more years experience as full time or clinical faculty member of a medical school. Some practice experience desirable. For further details send CV to: Thomas T. Amatruda, Jr., M.D., Clinical Director, Waterbury, CT 06720. W.H. is an equal opportunity employer.

Tablets
PERCODAN®
oxycodone with APC C II

Tablets
PERCODAN®-Demi
oxycodone with APC C II

Brief Summary of Prescribing Information

INDICATIONS For the relief of moderate to moderately severe pain.

CONTRAINDICATIONS Hypersensitivity to oxycodone, aspirin, phenacetin or caffeine.

WARNINGS Drug Dependence Oxycodone can produce drug dependence of the morphine type and, therefore, has the potential for being abused. Psychic dependence, physical dependence and tolerance may develop upon repeated administration of PERCODAN® and PERCODAN®-Demi, and it should be prescribed and administered with the same degree of caution appropriate to the use of other oral narcotic-containing medications. Like other narcotic-containing medications, PERCODAN® and PERCODAN® Demi are subject to the Federal Controlled Substances Act.

Usage in ambulatory patients Oxycodone may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. The patient using PERCODAN® and PERCODAN®-Demi should be cautioned accordingly.

Interaction with other central nervous system depressants Patients receiving other narcotic analgesics, general anesthetics, phenothiazines, other tranquilizers, sedative-hypnotics or other CNS depressants (including alcohol) concomitantly with PERCODAN® and PERCODAN®-Demi may exhibit an additive CNS depression. When such combined therapy is contemplated, the dose of one or both agents should be reduced.

Usage in pregnancy Safe use in pregnancy has not been established relative to possible adverse effects on fetal development. Therefore, PERCODAN® and PERCODAN®-Demi should not be used in pregnant women unless, in the judgment of the physician, the potential benefits outweigh the possible hazards.

Usage in children PERCODAN® should not be administered to children. PERCODAN®-Demi, containing half the amount of oxycodone, can be considered.

Salicylates should be used with caution in the presence of peptic ulcer or coagulation abnormalities.

PRECAUTIONS Head injury and increased intracranial pressure The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a pre-existing increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.

Acute abdominal conditions The administration of PERCODAN® and PERCODAN®-Demi or other narcotics may obscure the diagnosis or clinical course in patients with acute abdominal conditions.

Special risk patients PERCODAN® and PERCODAN®-Demi should be given with caution to certain patients such as the elderly or debilitated, and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, and prostatic hypertrophy or urethral stricture.

Phenacetin has been reported to damage the kidneys when taken in excessive amounts for a long time.

ADVERSE REACTIONS The most frequently observed adverse reactions include light-headedness, dizziness, sedation, nausea and vomiting. These effects seem to be more prominent in ambulatory than in nonambulatory patients, and some of these adverse reactions may be alleviated if the patient lies down.

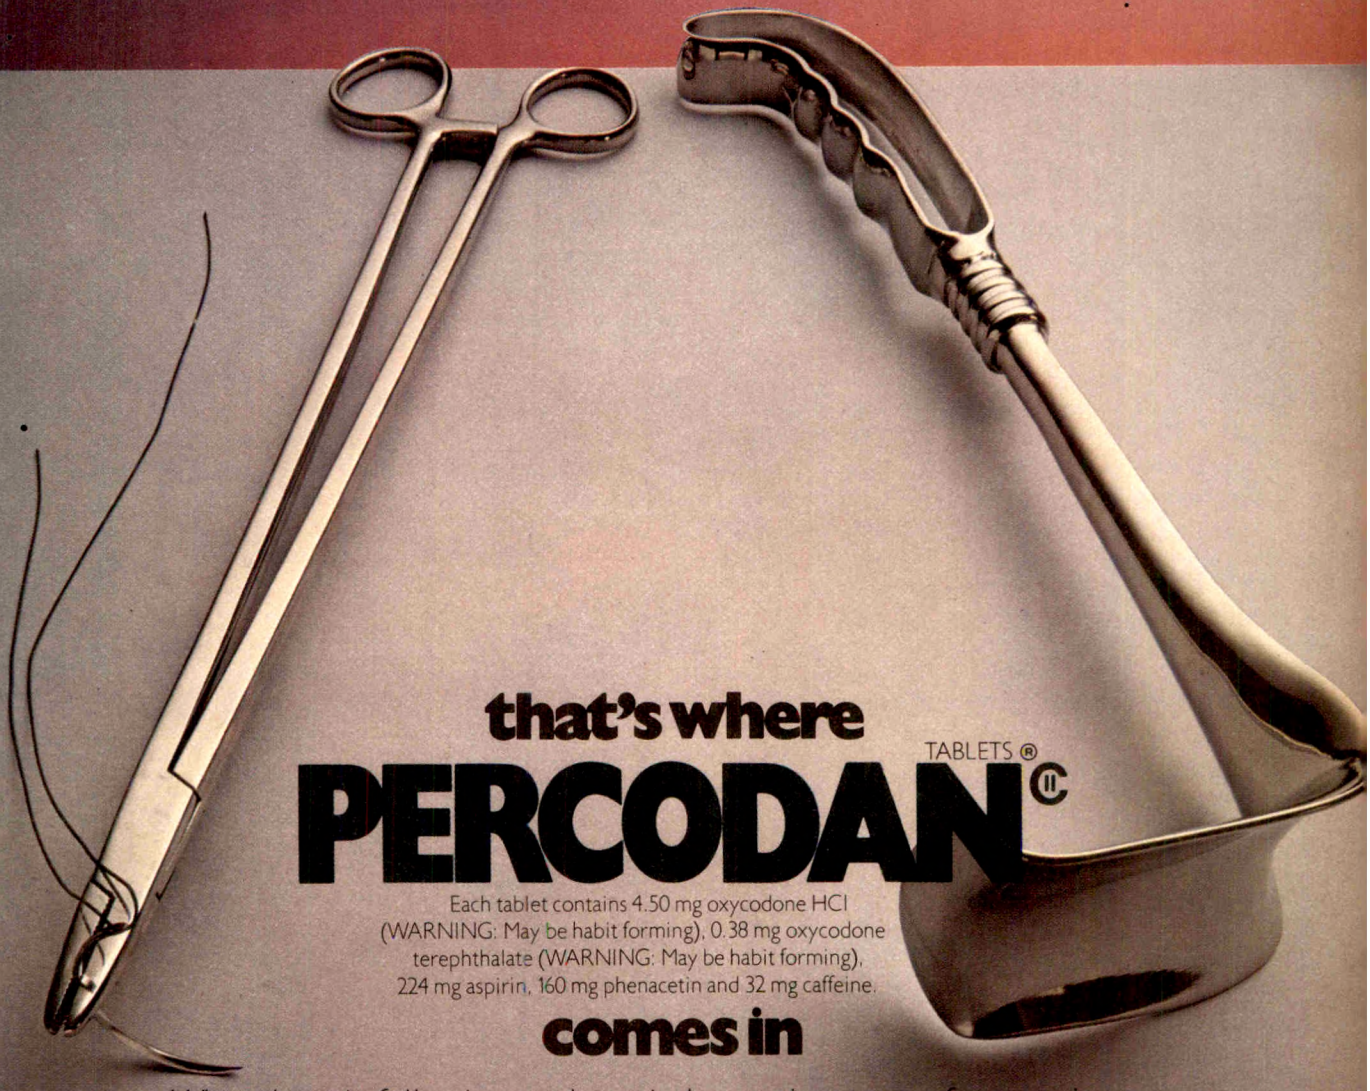
Other adverse reactions include euphoria, dysphoria, constipation and pruritus.

DOSAGE AND ADMINISTRATION Dosage should be adjusted according to the severity of the pain and the response of the patient. It may occasionally be necessary to exceed the usual dosage recommended below in cases of more severe pain or in those patients who have become tolerant to the analgesic effect of narcotics. PERCODAN® and PERCODAN®-Demi are given orally.

PERCODAN® The usual adult dose is one tablet every 6 hours as needed for pain.

PERCODAN®-Demi Adults—One or two tablets every six hours. Children 12 years and older—One-half tablet every six hours. Children 6 to 12 years—One-quarter tablet every six hours. PERCODAN®-Demi is not indicated for children under 6 years of age.

DRUG INTERACTIONS The CNS depressant effects of PERCODAN® and PERCODAN®-Demi may be additive with that of other CNS depressants. See WARNINGS.



Aspirin may enhance the effect of anticoagulants and inhibit the uricosuric effect of uricosuric agents.

Between an episiotomy and a hysterectomy, there's a lot of room for pain...

that's where

PERCODAN® TABLETS C II

Each tablet contains 4.50 mg oxycodone HCl (WARNING: May be habit forming), 0.38 mg oxycodone terephthalate (WARNING: May be habit forming), 224 mg aspirin, 160 mg phenacetin and 32 mg caffeine.

comes in

When the pain following an obstetrical procedure ranges from moderate to moderately severe, it's no time for inadequate analgesia. Consider PERCODAN.

Reliable—provides effective relief of moderate to moderately severe pain.

Acts rapidly—starts relieving pain usually within 15 to 30 minutes after administration.

Long-lasting—convenient q6h dosage provides up to 6 hours of comforting pain relief.

Economical—average day's dosage can cost less than most other leading oral narcotic analgesics.

and when less narcotic is needed PERCODAN®-Demi Tablets C II

Each tablet contains 2.25 mg oxycodone HCl (WARNING: May be habit forming), 0.19 mg oxycodone terephthalate (WARNING: May be habit forming), 224 mg aspirin, 160 mg phenacetin and 32 mg caffeine.

Information for authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

All articles published in this JOURNAL must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority.

Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article. They should include name of author(s), article title, name of periodical, volume, page, and year. Name of periodical should conform to that shown in latest *List of Journals Indexed in Index Medicus*. For reference style see current issue of JOURNAL. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2,* Current Investigation and Clinical Opinion, limited to *6,* and Current Developments, for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. **Do not send original art work, x-ray films, or ECG tracings.** Glossy print photographs are preferred, for good black and white contrast is essential.

Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the JOURNAL but may be submitted for paid advertisements, if desired.

Letters to the Editors. A brief Letter to the Editors commenting upon some article which has appeared in the JOURNAL will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

Natafort®

NEW IMPROVED PRENATAL VITAMIN AND MINERAL FORMULA!

Now contains 50 mg dioctyl sodium sulfosuccinate, 25 mg zinc and 100 mg magnesium—for improved patient care.

Natafort Filmseal® Tablets also provide important

- ■ antianemia factors: *iron* and *folic acid*
- ■ *calcium* and an increased amount of *vitamin C*
- ☐ B-complex vitamins: vitamins B_1, B_2, B_6, increased amounts of B_{12} and niacinamide
- ☐ other vitamins and minerals to help supply your patient's nutritional needs during pregnancy

PARKE-DAVIS

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, NJ 07950

PD-JA-2510-1-P(10-78)

In each reformulated Natafort Filmseal Tablet:

Vitamin A (acetate) (1.8 mg)	6,000 IU*
Vitamin D (ergocalciferol) (10 mcg)	400 IU*
Vitamin C (ascorbic acid)	120 mg
Vitamin B_1 (thiamine mononitrate)	3 mg
Vitamin B_2 (riboflavin)	2 mg
Vitamin B_6 (pyridoxine hydrochloride)	15 mg
Vitamin B_{12} (cyanocobalamin), crystalline	6 mcg
Folic Acid†	1 mg
Nicotinamide (niacinamide)	20 mg
Vitamin E (*dl*-alpha tocopheryl acetate) (30 mg)	30 IU*
Calcium (as calcium carbonate)	350 mg
Iodine (as potassium iodide)	0.15 mg
Iron (as ferrous fumarate)	65 mg
Magnesium (as magnesium oxide)	100 mg
Zinc (as zinc oxide)	25 mg
Dioctyl sodium sulfosuccinate	50 mg

*IU= International Units

†CAUTION—Folic acid may obscure pernicious anemia; the peripheral blood picture may revert to normal while neurological manifestations remain progressive.

USUAL DOSE: One tablet daily.

CAUTION—Federal law prohibits dispensing without prescription.

BETTER THAN EVER... NATAFORT

Tri-vaginitis effectiveness

BETADINE® Microbicides Vaginitis Regimen

kills all three pathogens that usually cause infectious vaginitis—monilia, Trichomonas and Haemophilus vaginalis

The broad-spectrum microbicidal action of BETADINE Microbicides kills all three pathogens that usually cause infectious vaginitis—*monilia, Trichomonas* and *Haemophilus vaginalis*. Agents that are aimed against only one specific pathogen may encourage emergence of others—but BETADINE Microbicides Vaginitis Regimen effectively attacks both single and mixed infections.

Effective, yet gentle

BETADINE Microbicides maintain microbicidal action in the presence of blood, serum and vaginal secretions. They are virtually nonirritating to vaginal mucosa and do not stain skin and natural fabrics.

Easy-to-follow regimen

In the office, swab the cervix and vulvovaginal area with BETADINE Solution which is promptly and decisively microbicidal. Prescribe BETADINE Vaginal Gel* (povidone-iodine), one applicatorful of which is to be inserted each night, followed the next morning by BETADINE Douche in therapeutic concentration. After two weeks of therapy, the patient may be instructed to return for an office visit. In more resistant cases, the regimen may be continued through 1 or 2 cycles, if necessary.

BETADINE® Solution
BETADINE® Vaginal Gel*
(povidone-iodine)
BETADINE® Douche

*BETADINE Vaginal Gel (povidone-iodine) has been evaluated as possibly effective for use in the management of *Trichomonas vaginalis* vaginitis, monilial vaginitis and nonspecific vaginitis.

See adjoining page for prescribing information.

Now available...
BETADINE® Douche Kit

For douching in the BETADINE Microbicides Vaginitis Regimen, you can now prescribe BETADINE Douche Kit for a complete douching system, or BETADINE Douche 8 oz. for use with a gravity-flow douche bag or bulb syringe.

BETADINE Douche Kit contains:

(1) BETADINE Douche concentrate for making the douche solution
(2) Comfortable-to-use, squeezable, plastic syringe bottle
(3) Anatomically-correct cannula
(4) Instruction booklet
— Complete, ultra-modern, convenient douching system
— Provides the benefits of microbicidal BETADINE Douche

For a therapeutic concentration using BETADINE Douche Kit, instruct the patient to: Pour one (1) tablespoonful of BETADINE Douche concentrate into the syringe bottle provided in the kit. Add lukewarm water up *to the top of the syringe bottle.* Attach nozzle and shake gently to mix. Douche, *then repeat the procedure.*

For a therapeutic concentration using BETADINE Douche 8 oz., instruct the patient to: Add two (2) tablespoonfuls to a quart of lukewarm water, for use with a gravity-flow douche bag or bulb syringe.

BETADINE® Vaginal Gel (povidone-iodine) Brief Summary

For use in the treatment of Trichomonas vaginalis vaginitis, monilial vaginitis and nonspecific vaginitis.

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows: possibly effective for use in the management of trichomonas vaginalis vaginitis, monilial vaginitis and nonspecific vaginitis. Final classification of the less-than-effective indications requires further investigation.

Precaution

If irritation, redness or swelling develops, discontinue use. The rare individual with history of iodine sensitization should not use this product, pending further investigation.

G. K. Hall offers important books.

☐ CARCINOID TUMORS:
A Clinico-Pathologic Study
Charles Marks, M.D., Ph.D.
0-8161-2141-9 $22.50
Discusses the clinical, pathologic, therapeutic, and radiologic aspects of the carcinoid tumor, and reviews endocrinologic components of the carcinoid syndrome.

☐ A PRIMER OF CANCER MANAGEMENT
Jacob Lokich, M.D.
0-8161-2102-8 $19.95
This important manual focuses on cancer care and the role of staff in the following areas: communication of the diagnosis and characteristics of the disease; application of therapeutic modalities; management of secondary symptoms; and the development of support services.

☐ DX AND RX:
A Physician's Guide to Medical Writing
John H. Dirckx, M.D.
0-8161-2100-1 $12.95
Provides specific guidelines for preparing technical material for publication.

". . . a splendid survey of the essentials of grammar . . . makes the topic not merely painless but positively enjoyable."

Fergon®
brand of
ferrous
gluconate

When she needs iron replacement

Fergon is ideal as iron replacement therapy for hypochromic anemia of pregnancy, because it provides the three advantages you want in oral iron therapy: excellent tolerance • proven effectiveness • economy.

Fergon encourages a rapid hemoglobin response and it is well tolerated and non-constipating in the great majority of patients. It is soluble throughout the entire pH range of the g.i. tract and is available for absorption at the upper intestinal site of maximum absorption.

Each tablet contains 320 mg (5 grains) ferrous gluconate equal to approximately 36 mg ferrous iron. Dosage: Adults, one or two tablets three times daily; Children, 6-12 years, one tablet one to three times daily, as directed by the physician. Supplied: Bottles of 100 and 1000. Each capsule contains 435 mg ferrous gluconate equal to approximately 50 mg ferrous iron. Dosage: Adults, one daily or as directed; Children, as directed. Supplied: Bottles of 30.

Our successors

Presidential address

WILLIAM J. DIGNAM, M.D.
Los Angeles, California

"SPEECHES ARE like babies—easy to conceive but hard to deliver" (anonymous) is an oft-repeated quotation, or as Smith[1] would have it: "Many physicians would prefer passing a small kidney stone to presenting a paper." I suppose that such concerns may well have application when one is addressing a group of strangers, and would-be critics, but they hardly apply to the presidential address of our society. Fortunately our society gives great latitude to its President regarding the type of address which is acceptable and it is, indeed, a great privilege and pleasure to be able to share a few thoughts with such a distinguished group of warm and loyal friends. I have chosen to comment upon the influences which are shaping the young gynecologists of our day, as I see them. I shall be brief, mindful of the warning of Southgate,[2] "Unfortunately, too many authors write as though they will never have another chance—and they are correct."

The laconic Smith[1] says, "There are many ways to deliver papers, the best way is to toss them on the front porch before sunup." I hope you will not share that feeling before I have finished.

One cannot, of course, escape a feeling of deep humility as he reflects upon the truly distinguished list of presidents who have preceded him to this podium, and one is tempted to borrow very heavily from the writings of these and other outstanding authors who are so facile with the written word.

No less a personage than Hippocrates (in his *Precepts*) has counseled us against quoting from the writings of others. "If for the sake of a crowded audience you do wish to hold a lecture, your ambition is no laudable one, and at least avoid all citations from the poets, for to quote them argues feeble industry." Feeble industry it may be indeed, but who of any judgment would not prefer the lilting phrases of the poets? I confess to a great fondness for such quotings. Who among us could phrase a recommendation for another physician so entertainingly as Auden?

> Give me a doctor partridge—plump,
> Short in the leg and broad in the rump,
> An endomorph with gentle hands
> Who'll never make absurd demands
> That I abandon all my vices
> Nor pull a long face in a crisis,
> But with a twinkle in his eye
> Will tell me that I have to die
>
> *W. H. Auden*
> *Footnotes to Dr. Sheldon*

Yes, even the announcement of a fatal disease can be made much more bearable by the compassionate physician. The compassionate physician Dunn[3] has stated it

Presented at the Forty-fifth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Gleneden Beach, Oregon, September 26-30, 1978.

Reprint requests: Dr. William J. Dignam, Department of Obstetrics and Gynecology, University of California Los Angeles Medical Center, Los Angeles, California 90024.

0002-9378/79/100115+05$00.50/0 © 1979 The C. V. Mosby Co.

so well to this society: "But, to care for our patients with compassion and to give of ourselves as one human being to another is a gift of God that no computer invented can ever satisfy."

Are there influences at work which might deprive society of its compassionate physicians? I think that there are. The first is the selection of students to study medicine. This has been the subject of extensive commentary and the cause of personal grievance for many a family, including many a physician's family. How often have we known a superb young man or woman who would clearly make a superb and compassionate young physician, only to find that some several apparently whimsical admissions committees have denied that student admission to medical school?

It is difficult to fault the admissions committees because few would deny that, "In diagnosing the illness of the sick, logic would dictate, physicians of high intellectual competence will be right more frequently than less talented physicians. Most of us in selecting our own physician will prefer a bright one to a dull one."[4]

The grade inflation extant in our colleges and universities today is well recognized. Thus a recent article in *The Atlantic Monthly* states: "Grade inflation is also epidemic. At Harvard, where one must assume resistance to this is greater than average, 85 percent of the class of 1977 graduated with honors, as compared with 39 percent of the class of 1957. Also, according to a recent report of the Harvard administration, 85 percent of all grades given there last year were B-minus or higher (compared with 70 percent in 1965-66)."*

Thus a typical medical school will be presented with 4,000 applicants for an entering class of 150 to 200 and at least 300 of them will have a grade point average of 3.7 or higher on their college transcripts. It is quite understandable that admissions committees feel that it is probably unnecessary to accept applicants with much below an A− average in order to admit a group of students who have appropriate personal characteristics *and* exceptional intelligence. These committees, however, must recognize that today applicants with high grade point averages do not necessarily have exceptional intelligence and that it is very difficult to appraise personal characteristics. Psychological testing for the selection of students has been tried and found wanting.

Certainly the interview system currently in vogue at many medical schools is not foolproof. Repeatedly students are admitted who are lacking in the personal characteristics necessary to permit them to function effectively in the clinical setting, not to mention those for whom the stresses are too great, and suicide results.

*From Chase, A.: Skipping through college The Atlantic Monthly, September, 1978, p. 34.

Not all medical students are destined for careers in *clinical* medicine and clearly the medical schools must provide opportunities for these individuals also, but present custom leaves the choice of field of endeavor to the individual, not to the institution, so that some individuals with superior intelligence but inadequate personal traits end up practicing clinical medicine.

One factor which makes the interview system difficult is the volume of applications which must be considered. Many of us have known single admissions officers who conducted the entire admissions process of a given school—judging personality traits by means of personal interview and evaluation of letters of recommendation. Many of these individuals had superb judgment. Now, however, the large volume of applicants virtually precludes this mechanism. Instead we have large committees and the variation in judgment among the members is introduced. It is a shame that the volume of applications has caused this situation because there are clearly a number of sterling individuals whose judgment and experience would qualify them very well to pick a medical school class. I should be delighted to have Dr. Dan Morton choose the entire generation of physicians to care for my children and their families and I know that he could do it single-handedly.

It may be that our society as an organization can have little influence on the selection of appropriate medical students, but certainly as individuals we can have an influence. Many groups and individuals associated with admissions committees show increasing interest in the selection of students with desirable personal characteristics and we can emphasize that attitude. Our letters of recommendation can be much more specific and avoid general platitudes. We can recruit appropriate students to the profession.

What of the attraction of well-motivated students to our specialty? Here we can have a major influence. It has become increasingly clear to me in interviewing residency applicants that one of the principal factors attracting students to obstetrics and gynecology, or to any other field for that matter, is the example of an instructor. Time and again I have heard: "I am attracted to obstetrics and gynecology because I noticed that Dr. X was so interested in his patients and they had such warm feelings towards him. It is not like some of the other specialties where a doctor does an excellent job technically, but then returns the patient to her referring physician and has no further interest in her. Obstetrics and gynecology has all the advantages of family practice but also has all the advantages of a specialty."

We can be even more considerate of these young

students as we see them in our offices and in our hospitals. Just a little time will often spark a developing interest.

I believe that our society could also encourage medical students by permitting or sponsoring a few of them to attend our meetings. Our society is unique and its spirit of fellowship is very warm and impressive. Students should be exposed to the joys of association with these compassionate physicians.

Again, the compassionate physician. So many of our patients require only that. They require a physician who is so compassionate that he will not saddle them with some arbitrary diagnosis when he is unable to discover the cause for their symptoms, or who will not contribute the necessary time to hear out a very anxious person. And yes, as Auden has suggested, some few of our patients must be escorted gracefully to their deaths. Even so somber a matter as dying can be made so much less somber by the poets.

> Die I must, but let me die drinking in an inn!
> Hold the wine-cup to my lips sparkling from the bin!
> So, when the angels flutter down to take me from my sin,
> "Ah, God have mercy on this sot," the cherubs will begin.
>
> *Walter De Map*

Who among us can raise the spirits of a patient so quickly and surely? Even the *Nonsense Verses* of Burgess remove us instantly from our daily cares.

> I'd rather have Fingers than Toes,
> I'd rather have Eyes than a Nose,
> And as for my Hair
> I'm glad it's all there,
> I'll be awfully sad when it goes.
>
> *Gelett Burgess*
> *Nonsense Verses*

> I never saw a Purple Cow,
> I never hope to see one;
> But I can tell you anyhow,
> I'd rather see than be one.
>
> *Gelett Burgess*
> *The Purple Cow*

> Ah, yes, I wrote the "Purple Cow"—
> I'm sorry, now, I wrote it!
> But I can tell you, anyhow,

Hippocrates would have loved him—a poet who does not wish to be quoted.

What about our specialty? Will it be the same in the future if the compassionate young physicians are attracted into it? There are both external and internal influences which could produce some significant changes in their patterns of practice. Changes in patterns of practice may be very good if they result in better care for our patients. They can be very bad if the reverse is true.

Most of us feel that the development of the specialty of obstetrics and gynecology was a significant advance and that it has clearly resulted in better care for the female members of our population. A number of studies have indicated that women consider gynecologists as their personal physicians and turn to these gynecologists with *all* of their medical problems. However, better care will result only if gynecologists are informed about *all* of the problems and symptoms presented, and for the population as a whole, better care will result only if *all* women have access to suitable care.

A number of influences are at work and will have their effects on these considerations. With the elimination of the internship and the entry of the great majority of medical students into specialty training directly after medical school there is a clear possibility that our residents will be too narrowly trained unless we are very careful to include appropriate training within our residencies in obstetrics and gynecology. The American Board of Obstetrics and Gynecology[6] requirements state: "The candidate beginning graduate education in 1976 will be required to have completed not less than four years in approved clinical programs, with not less than 36 months of progressing responsibility for the care of obstetric and gynecologic patients, including the usual time as 'chief resident' in the program. Completion of a year of 'internship' plus a three year residency program will fulfill this requirement.

The Board recommends that the candidate intending to practice as an obstetrician and gynecologist spend a significant proportion of graduate education in a broadly oriented approach to patient care."[5]

Other influences would constantly narrow the field of activity of the obstetrician-gynecologist. Some come from outside the specialty and others from within the specialty.

Other groups of physicians see themselves as the logical individuals to care for some of our patients. For example, family practitioners are being trained to care for common gynecologic problems and normal obstetric problems, but the definitions of "common" and "normal" are inexact and "normal" may become "abnormal" quickly and unexpectedly. What of the second opinion? A consideration of hysterectomy for a patient with abnormal bleeding may be a common problem but

should a second opinion concerning the advisability of hysterectomy be given by a family practitioner? Some of them think so, but not all of us would agree.

The field of emergency medicine is developing rapidly. Legislation is appearing requiring that hospital emergency rooms have full-time physician staffing. This is laudable for the care of patients with true acute emergencies. However, many of the patients who present themselves to emergency rooms do not have acute emergencies but have simply chosen this avenue as the most practical way to see a physician. Who should care for those patients and who should determine the necessity for admission to the hospital or for transfer of the care of that patient to another physician? Many of us think we should make these decisions.

From within our specialty changes are occurring which might restrict the activities of our resident graduates in the future. The subspecialties have appeared—gynecologic oncology, maternal-fetal medicine, and reproductive endocrinology. Would it be possible for our specialty to be divided into many subgroups? Possible, but I think unlikely. Internal medicine has gone that route and now, based in part on deficiencies which have come to light, programs in general internal medicine are reappearing. We could learn from this experience. We have at least avoided the difficulty of creating independent boards and our subspecialists have received certificates of special competence with a continuing emphasis on the necessity of having competence in general obstetrics and gynecology before and after receiving the special certificate. Still there remains the significant concern that particular procedures may in the future, not be authorized for those not holding the special certificates and so there are concerns about the numbers of these certificates being awarded. In June, 1978, the written examination in gynecologic oncology was passed by 35 candidates; the examination in maternal and fetal medicine, by 76 candidates; and that in reproductive endocrinology, by 55 candidates. Past experience indicates that not all of these individuals will also pass the oral examination. For example, in 1977, the oral examination in gynecologic oncology was passed by 29 candidates; that in maternal-fetal medicine, by 37 candidates; and that in reproductive endocrinology, by 14 candidates. It seems likely that the numbers of candidates will not increase markedly in the near future.

Our specialists themselves have taken steps which reduce their spheres of activity. I refer to the relinquishing of certain tasks to midwives, nurse-practitioners, childbirth instructors, and other individuals. Originally much of this was done to combat the shortage of physicians but that shortage is rapidly disappearing. In 1953, there were approximately 135 active physicians per 100,000 persons in the United States. By 1985, there will be 200 and by the year 2000 there will be approximately 260 physicians per 100,000 individuals or one for every 385—and this estimate may be conservative.[6] Now, however, some of our specialists have become accustomed to delegating some tasks and they no longer see their patients with vaginal discharge, or the patients with questions about normal pregnancy, or the patients who come in for periodic examinations, or those with questions about sexual problems. At times one wonders about which patients they *do* see. One also wonders about the patients who complain of vaginal discharge but are worried about the possibility of cancer and would like to discuss it with their compassionate physicians.

So we see that our young graduates are pulled in both directions. The requirements of their certifying board and the realities of women turning to them with all of their medical (and sometimes other) problems require that our specialists remain well informed about general medicine—and well they should. The great majority of surgical specialties have a corresponding medical specialty and frequently the diagnostic aspects of the patient's management are carried out by the medical specialists while the surgical specialist confines his interest to the surgical treatment of the patient. Obstetricians and gynecologists, however, take the responsibility for both the medical and surgical aspects of their patient's problems.

On the other hand, the possibility exists that certain of the activities traditionally performed by obstetrician-gynecologists may be performed by others in the future, thus narrowing the sphere of activity within the specialty.

If one gave away the complicated problems to the subspecialist and the "simple" problems to the various physician extenders, the practice in our specialty would certainly be different from that which we have known and I question that it would be as interesting. Our society can do much to keep that from happening and I feel that it is uniquely qualified to do so.

I have stated that the Pacific Coast Obstetrical and Gynecological Society is different, and indeed it is. Our founding fathers had so much wisdom. They did not found an association, or an academy, or a section, but a "society." "Companionship or association with one's fellows; usually friendly or intimate intercourse; company" are Webster's definitions. "Society" is derived from the Latin *societas,* "meeting an associate." How appropriate that is for our organization. Our title is not as imaginative as some. Consider, for example, Ancient Mystic Order of Bagmen of Baghdad, Concentrated Order of Hoo Hoo, or Iridescent Order of the Iris. The latter is so impressive that it moved a journalist in

Springfield, Missouri, to write in 1914: "Just think of it. The Magnanimous Supreme Ruler of the Iridescent Order of the Iris was arrested in New York City the other day and thrown into a horrid jail! There must be something awfully wrong with the laws when such things can be done to a man with such a lovely title."

The Order of Pink Goats was organized in 1919. The members appeared in public in pink pajamas and gowns, carrying goats of all kinds and descriptions. The supreme officer was known as He Goat and some of the other titles were Little White Goat, Chief Bleater Goat, Chief Billy Goat, Chief Wise Goat, Goat Getter, Inner Angora Goat, Bell Goat, and Musical Goat.

I believe that my favorite is the Ancient and Honorable Order of the Blue Goose. It was founded in 1906 B.P. (i.e., before prohibition) mainly for "fun and sociability." What other organization can boast of Most Loyal Gander (president), Supervisor of the Flock (vice president) Custodian of the Goslings (warden) Wielder of the Goose Quill (secretary), and Keeper of the Golden Goose Egg (treasurer)?

But what is the nature of *our* society? Certainly it is viewed differently by different observers. Some would have us be a straight-forward scientific society with our programs limited to the presentation of scientific reports. There are many forums for such presentations and it is doubtful that there is a need for one more of the stereo-typed variety. Can the Pacific Coast Society offer anything different or of value greater than that of the multitude of scientific meetings and postgraduate courses? Yes, I think that it can, and I believe that the format of our meetings is a very important factor. Despite the attempts of many organizers to make it possible to discuss the presentations with the speakers it is rarely possible to pursue these discussions in sufficient detail because the formality of the meeting, or the size of the meeting, or the limited time prevents it.

How much better it is to be able to spend several days with the speakers and to have a number of informal opportunities to discuss their reports. This is one of the principal reasons for keeping our meetings from growing too large. Many organizations have started with a small group of truly interested members and during those early years discussion was productive and progress was great but now that the societies are larger the members reflect wistfully upon the early, stimulating days, or they look regretfully upon the formation of a new society of "Young Turks" who have become dissatisfied with the status quo. Our founders and early members have shown great wisdom in keeping the society small but also maintaining a steady flow of young, vigorous members into the group.

At so many medical meetings one sees the subspecialists presenting papers to their own group, discussing those papers with each other, and then returning home without having had much contact with members who do not share their particular interest. The result is that many of the physicians who manage all of the problems in the specialty begin to think that they are not qualified to understand the topics under discussion and gradually stop attending those sessions.

How much better is the atmosphere at the meetings of the Pacific Coast Obstetrical and Gynecological Society. It is not broken up into small groups and almost everyone in attendance hears all of the papers. If something is not clear or is controversial there is plenty of time for discussion and there is virtually endless opportunity for clarification—at the poker table, the golf course, or, yes, even the hospitality room.

Medical practice should be far from just work. I do not know of a group who goes about their daily activities with so much fervor and downright enjoyment as do physicians. But even we can be guilty of "all work and no play." Our society also helps with the maintenance of the balance between these two but lest any of you has not received that message I shall leave you with just one more quotation, whose author, unfortunately, is unknown.

If you hold your nose
To the grindstone rough
And hold it there
Long enough
In time there will be
No such thing
As brooks that babble
And birds that sing
Of these three things
Your world will compose
Just you, the stone
And your damned old nose.

The hemodynamic and metabolic responses to endotoxemia were assessed in seven splenectomized, chronically instrumented, conscious but lightly sedated beagle dogs. Measurements included: cardiac output (CO), right and left atrial pressures (RAP, LAP), systemic and pulmonary arterial pressures (SAP, PAP), and heart rate (HR). Arterial blood samples were measured for blood gas tensions, pH, lactate, and pyruvate. After a brief control period, 1 mg/kg endotoxin (Difco 026:B6) was given as an intravenous bolus. Two hours later, each animal was treated with low–molecular weight dextran (LMDX), 2 ml/kg/min for 15 minutes. Endotoxin initially produced a precipitate decline in CO, HR, RAP, LAP, and SAP with concurrent pulmonary hypertension; both pulmonary and systemic vascular resistance increased significantly, then declined to control values as the animal partially recovered. A progressive metabolic acidosis with excess lactate accumulation developed. LMDX produced a significant increase in CO, SAP, PAP, and LAP with a decrease in HR; RAP increased slightly. With hydration, hemodilution was noted along with relief of the metabolic acidosis and the oxygen debt. We conclude (1) neither pulmonary nor systemic vasconstriction persisted in the shocked dog, (2) the response of the pulmonary and systemic vascular beds to endotoxin was qualitatively similar, and (3) oncotic fluid therapy appeared to restore the hemodynamic and metabolic parameters to preshock values. (AM. J. OBSTET. GYNECOL. 134:120, 1979.)

A VERITABLE AVALANCHE of publications concerned with the basic pathophysiology and clinical management of shock, more specifically gram-negative endotoxin shock, has appeared over the past two decades. While much in experimental animal studies is of questionable relevance to human disease because of the artificiality of the experimental system (as well as species specificity), it is nonetheless pertinent to observe that provocative findings in the experimental animal do lead to appropriate research in humans.

Unfortunately, much of the artificiality referred to concerns the use of acutely instrumented mongrel animals, often of poor quality, anesthetized, artificially ventilated, sedated with various combinations of barbiturates and opiates, and often subjected to extensive major surgical procedures, heparinization, and other variables which influence the preparation significantly.

The present report deals with the preliminary results of an ongoing effort designed to reassess the typical hemodynamic and metabolic changes which follow the administration of *E. coli* lipopolysaccharide in a chroni-

cally instrumented, conscious population of beagle dogs. The response of this population of control animals will be used to contrast the responses of a similar population of animals treated before and after shock with various vasoactive amines and humoral modifiers.

Material and methods

Beagle dogs of either sex, 6 to 7 months of age, and of uniform weight (average 8.0 kg) were obtained from a supplier* and evaluated carefully over the next 4 weeks in a certified experimental animal facility for anemia, parasitic infestations, intercurrent disease, or other processes which might interdict their use. Thereupon, each animal was prepared in two stages.

Stage 1 included a left lateral thoracotomy and pericardiotomy under general anesthesia (1.5% halothane and a 50/50 mixture of nitrous oxide and oxygen) utilizing a Bennet BA-4 respirator. The pulmonary artery (PA) was dissected free of the aortic arch and a precalibrated electromagnetic flow meter transducer† of appropriate size was placed about the PA to measure cardiac output. A precalibrated 3.5 mm outside diameter micropressure transducer‡ was secured in the left atrium to measure left atrial pressure. The chest wound was repaired after exteriorizing the silicone rubber–invested wire leads; these were buried subcutaneously. The spleen was then exposed through a midline incision in the upper abdomen, decompressed by the injection of 0.1 ml of a 1:1,000 epinephrine solution into the splenic artery, then removed. The animal was allowed to recover over the next 2 to 3 weeks.

In Stage 2 each dog was premedicated with morphine sulfate, 1 mg · kg^{-1} body weight. An endotracheal tube was inserted to ensure an adequate airway. The femoral artery was exposed under local anesthesia and cannulated with a polyvinyl catheter in order to measure systemic arterial pressure and to collect arterial blood samples. The electromagnetic flow meter and micropressure terminals were exposed and connected to a physiologic amplifier.*

A triple-lumen 7 Fr. Swan Ganz balloon catheter was floated down on the exposed jugular vein into the pulmonary artery. Location was assured by monitoring the characteristic pulsatile waveform. Pulmonary arterial pressure and pulmonary artery wedge pressure were obtained through the distal port. The proximal port, 20 cm from the distal port, lay within the right atrium

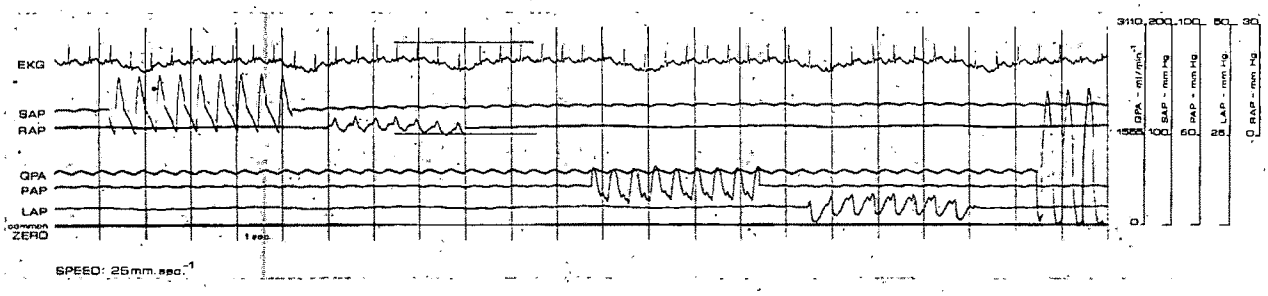

Fig. 2. Analogue signal display of six simultaneous hemodynamic parameters. Pulmonary artery flow *(QPA)*, SAP, PAP, and LAP, all have a common zero baseline; RAP zero centered 50 mm ↑. Scalar values on right-hand ordinate appear for each parameter. Phasic swings in electrocardiogram signal reflect respiratory rate. Pulsatile and electronically average signals are displayed.

and it was connected to another pressure transducer to measure the right atrial pressure. This pressure was considered the hydrodynamic equivalent of central venous pressure. The zero reference level for systemic arterial, pulmonary, and right atrial pressures was assumed to be the animal's midsternum as it lay in the lateral recumbent position. Finally, a standard limb Lead I electrocardiograph was attached. The complete preparation is illustrated in Fig. 1.

After a 30 minute control period, each animal was shocked with the intravenous bolus administration of 1 mg · kg^{-1} *E. coli* lipopolysaccharide (Difco 026:B6, lot 613872); the toxin was administered over a 15 second interval. A continuous recording of the changes in flow, pressure, heart rate, and electrocardiogram was made over the next 5 minutes. Another set of values were made at 15 and 30 minutes after the toxin had been administered and thereafter at 30 minute intervals for a total elapsed time of 2 hours. Thereupon, a 10% solution of low-molecular weight dextran (Rheomacrodex; LMDX-40) in saline was administered through a forelimb vein at a rate of 2 ml · kg^{-1} · min^{-1} over a 15 minute interval. Hemodynamic data were measured at the end of the infusion and again 45 minutes later. The animal was killed with a supersaturated solution of potassium chloride and the electromagnetic flow meter transducer and micropressure transducer were recovered; the relative position of the Swan Ganz catheter in the heart was ascertained.

Arterial blood samples were obtained during the control period, again at 1 and at 2 hours after administration of the toxin, and just prior to terminating the experiment. Blood gas tensions (O_2 and CO_2) and blood pH were measured*; hematocrit was also measured. Base excess was calculated from the Siggaard-Andersen nomogram. Arterial lactate and pyruvate were measured using standard kits* and excess lactate, a measure of oxygen debt, was calculated by the method of Huckabee.[1]

Both pulsatile and electronically averaged (mean) pressure and flow signals were displayed and allowed simultaneous measurement of systemic arterial pressure (SAP), right and left atrial pressures (RAP, LAP), pulmonary artery pressure (PAP), and, intermittently, pulmonary artery wedge pressure (PAWP), as well as heart rate (HR) and cardiac output. Total pulmonary vascular resistance (TPR) and total systemic resistance (TSR) were derived from standard formulas wherein resistance is the quotient of pressure (in millimeters of mercury) × 100 divided by flow (in ml · min^{-1}). Resistance was expressed as Green's[2] peripheral resistance units.

Results

Resolution of surgical and technical problems. Almost two thirds (19/33) of the dogs suffered major surgical and postoperative complications (hemorrhage, sepsis, wound disruption, and death). Much of this was the result of surgical inexperience and improper implantation of the atrial micropressure transducer as well as not allowing the animals sufficient time to recover from the earlier surgery. More recent experiments have been successful and we have complete data on seven dogs. Detailed statistical analysis is pending completion of an additional three animals.

Possibly the most troublesome biophysical signal was that obtained from the micropressure transducer in the left atrium. Zero baseline shift and drift were observed which were compensated for during the control period by using the PAWP as the reference standard to which the mean left atrial pressure was matched. No future adjustments in LAP signal were made thereafter as any

*Model IL, No. 213 digital pH blood gas analyzer, Lexington, Massachusetts.

*Sigma Chemical Co., St. Louis, Missouri.

discrepancies in the shock interval were considered physiologic and not artifactual.

Fig. 2 depicts the typical analogue signals obtained with the VR-6 physiologic recorder. All signals were calibrated from a common zero to a 100 mm full-scale deflection except for (1) the unquantified electrocardiogram display and (2) the RAP zero, which was arbitrarily placed in the center of the strip (i.e., 50 mm up from the common zero). Pulsatile and electronically averaged signals were displayed.

Changes in hemodynamics. The changes in both mean cardiac output (equal to pulmonary artery flow) and heart rate are illustrated in Fig. 3. The changes from control status, over the next 5 minutes following the injection of endotoxin and over the next 2 hours as well as the response to low–molecular weight dextran, are plotted. The profound fall in cardiac output was accompanied by a fleeting tachycardia whereupon the heart gradually decelerated (−20 bpm). The nadir of the response was invariably reached in the first 5 minutes. Thereafter the animal partially recovered so that 75 to 90 minutes later cardiac output had been partially restored to preshock levels and a significant tachycardia was evident; cardiac output then began to decline while HR remained elevated. A dramatic increase in cardiac output and a concomitant fall in HR characterized the response to the infused dextran.

Fig. 4 illustrates the changes in mean systemic and pulmonary pressure in this same group of seven dogs. Delta (Δ) SAP, the *net* pressure across the systemic vascular bed, was derived from the mathematical difference of SAP minus RAP. Since RAP is a relatively trivial value when compared to SAP, ΔSAP is not significantly different from mean SAP. The change in SAP was characteristic: A profound hypotension occurred initially, with little evidence of recovery, then a persistent hypotension developed which was corrected dramatically with the dextran. In contrast dextran barely increased RAP (<6 mm Hg); mean atrial pressure was still well within the physiologic range.

ΔPAP, the net pressure across the pulmonary vascular bed, equal to mean PAP minus LAP, is similarly depicted in Fig. 4. Pulmonary hypertension developed immediately after the injection of endotoxin and was associated with a significant fall in LAP. The changes persisted for another 45 to 60 minutes, then returned toward preshock values. The dextran initially produced a sharp increase in PAP and LAP but the former was not persistent, returning to preinfusion levels.

A comparison of the changes in systemic and pulmonary vascular resistances is depicted in Fig. 5. The resistance calculations assume that left ventricular output is

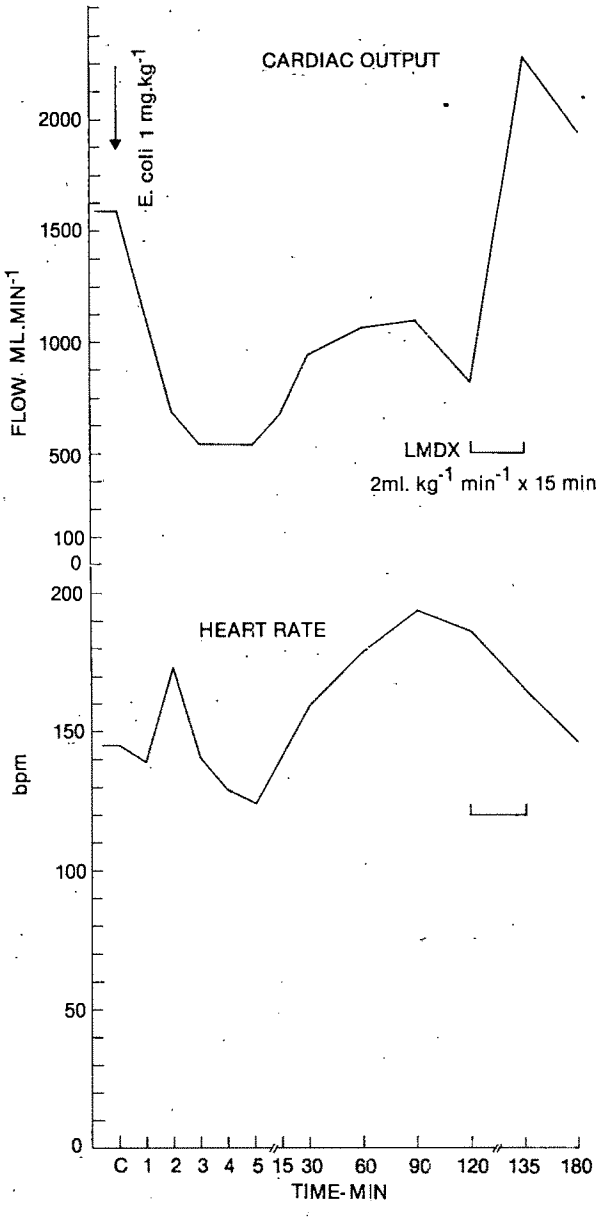

Fig. 3. Effect of intravenous endotoxin on mean cardiac output and heart rate in seven dogs, emphasizing acute dchanges over first 5 minutes and over 2 hours and the response of the shocked animal to low–molecular weight dextran.

equal to the measured right ventricular output, and thus that fraction of left ventricular output which feeds the coronary arteries (and which may be relatively substantial in the shocked animals) is not taken into account. Thus, TSR is inherently underestimated. Nonetheless, the significantly lower control values in the pulmonary bed as compared to the systemic vascular bed are consistent. At first glance, it is evident that both vascular beds appeared to behave in a similar manner, with the peak TPR being slightly (1 minute) later than

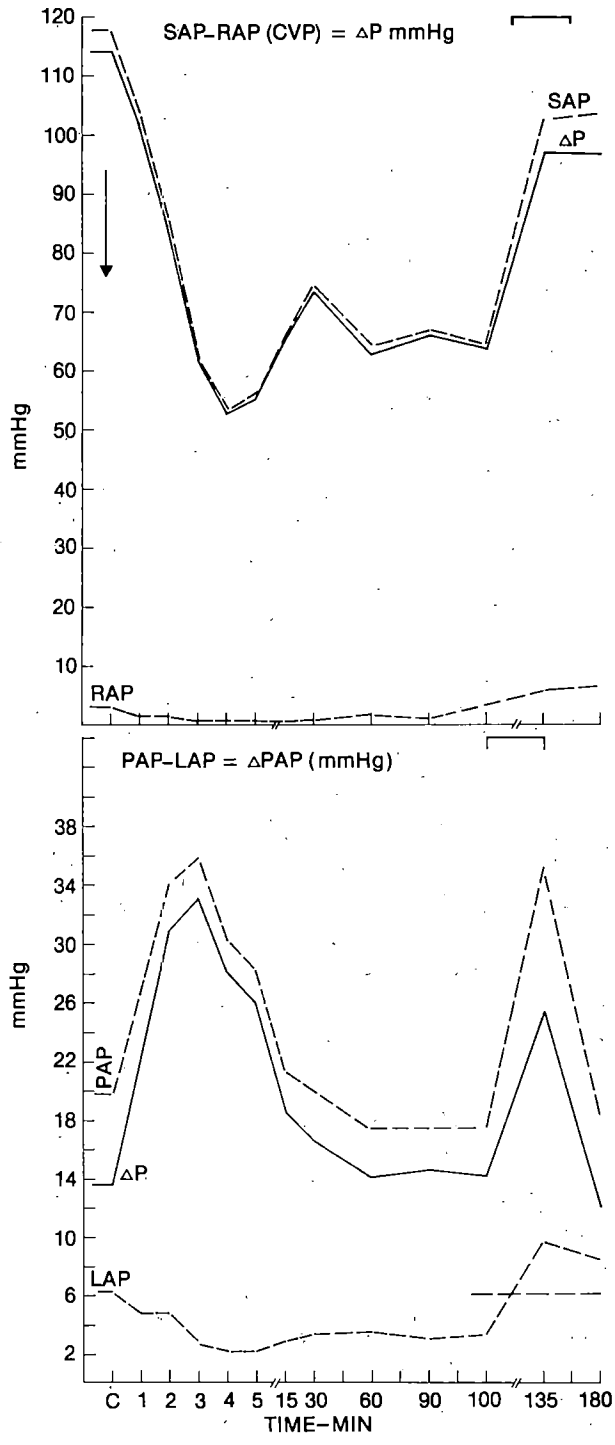

Fig. 4. Effect of intravenous endotoxin on mean SAP, RAP and ΔP (SAP − RAP) as well as pulmonary vascular equivalents (PAP, LAP, and ΔP = PAP-LAP) in seven dogs. Whereas RAP shows little increase with LMDX, note significant change in PAP, LAP, and ΔP.

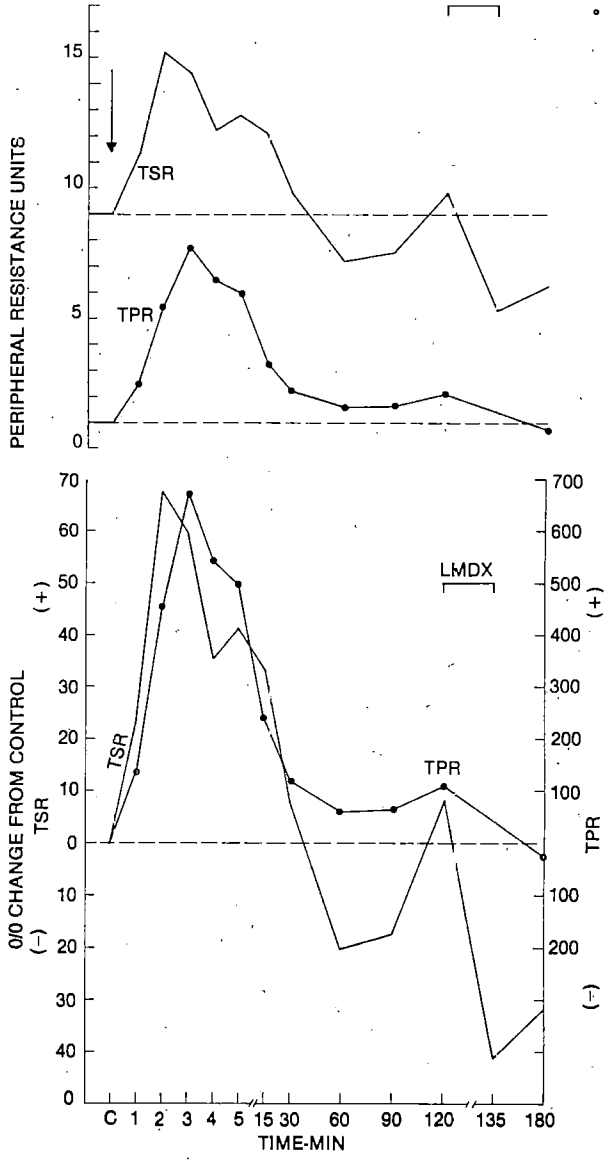

Fig. 5. Effect of intravenous endotoxin on mean TSR and TPR in seven dogs as well as response of shocked dogs to LMDX. Data are also plotted as percent change from control; note tenfold difference in scalar ordinates.

the peak TSR. Both resistances returned to control values about 60 minutes later, with the TSR falling below control levels during the relapsing phase. The response to the volume overload was striking and consistent in each animal: a significant fall in TSR with little change in TPR. The extent to which this fall in TSR reflects an alteration in blood viscosity and rheology rather than an inhibition of peripheral sympathetic activity in response to baroreceptor stimulation[3] is speculative. Nonetheless, the dissimilarity in the two vascular beds is noteworthy.

While a comparison of the changes in vascular resis-

Table I. Changes in arterial blood pH, blood gases (oxygen and carbon dioxide), hematocrit (Hct), base excess (BE), and selected metabolic parameters (arterial lactate, pyruvate, and computed excess lactate) in the shocked dog and after volume therapy

Parameter	*Control*	*S + 60*	*S + 120*	*D + 60*
pHa (units)	7.35	7.30	7.33	7.34
Pao_2 (torr)	109	75	98	82
$Paco_2$ (torr)	51	42	36	45
Hct (vol %)	38	42	41	27
BE (mEq/L)	+1.4	−5.5	−6.3	−1.4
Arterial lactate (mg/100 ml)	11.2	25.1	27.7	19.3
Arterial pyruvate (mg/100 ml)	1.04	1.76	1.43	1.54
Excess lactate (mg/100 ml)	—	6.70	10.3	2.62

S + 60 and S + 120 denote time in minutes after 1 mg · kg^{-1} of an intravenous bolus of *E. coli* lipopolysaccharide and D + 60 is the time in minutes after administration of LMDX−40, 2 ml · kg^{-1} · min^{-1} x 15 minutes.

tance does suggest a qualitative similarity, the true assessment of the *quantitative* disparity is reflected by expressing the resistance changes as a percentage of control. Percent changes in TSR are shown (in Fig. 5) in the left-hand ordinate and those for TPR are in the right-hand ordinate. The scalar changes in TPR are tenfold those of the TSR. The increased sensitivity of the pulmonary vascular bed to endotoxin when compared to the systemic vascular bed is re-emphasized. Exactly how different components of the systemic vascular bed (i.e., liver, kidneys, gut, and muscle) behave cannot be derived from this experiment.

Metabolic changes. The metabolic indices and response to shock and to volume therapy are summarized in Table I. The occurrence of a progressive metabolic acidosis and of lactate accumulation, reflecting an increasing oxygen debt, is demonstrated. The hemodilution secondary to volume therapy may have contributed to the *apparent* reduction in metabolic acidosis and oxygen debt but also may well reflect improved tissue perfusion, oxygenation, and aerobic metabolism.

Comment

This study, still in progress, was designed to establish a uniform experimental animal model for the study of endotoxic shock in which the usual variables of acute surgery, i.e., anesthesia, ventilatory support, vasoactive drug (barbiturates), heparinization to maintain catheter patency, uncontrolled blood sampling, and the like, are minimized. That objective appears to have been accomplished so that our next goal—to determine what role the prostaglandins play in the pathophysiology of endotoxic shock—can be approached. Recent studies suggest that the genesis of pulmonary hypertension in septic shock in the dog,[4-6] cat,[7] and sheep[8] is mediated by the prostaglandins.

While it would have been tempting to use, as a control population, the findings reported[9, 10] several years ago by one of us (J. A. M.) in an acutely instrumented, anesthetized, and artificially ventilated population of mongrel dogs with intact spleens, we elected instead to revalidate that report with the present model. Surprisingly, perhaps, the current findings are comparable except in two regards. First, pulmonary hypertension and pulmonary vascular resistance appeared to be persistent and biphasic in the mongrel dog. While both parameters increased in a similar manner immediately after the administration of endotoxin in both groups of dogs, PAP and PVR were reported[9, 10] to be sustained in the mongrel dog and did, in fact, appear to increase again as the animal relapsed. No such persistent or biphasic effect has been noted in the beagle dog. The genesis of the pulmonary changes is still speculative and has been attributed to a variety of stimuli, i.e. (1) a reflex neurogenic vasoconstrictor response to microembolization (platelet aggregation?) and (2) the release of humoral vasoactive substances (histamine, serotonin, prostaglandins). Whatever the stimulating factor(s), the present studies do not suggest that the alterations in the pulmonary and systemic vascular beds are dissimilar except in a quantitative manner with the former seemingly more intense.

Second, whereas hemoconcentration developed in the mongrel after shock, such was not the case in the beagle. Earlier it was thought that the hemoconcentration developed as plasma leaked across damaged endothelium.[10] The data in the splenectomized beagle do not support that premise, at least not during the 2 hour shock interval. Most likely, the postshock increase in hematocrit observed previously was due to splenic contraction whereby 8 ml · kg^{-1} · body weight of red blood cells may be added to the circulation.

The genesis of the acute reduction in cardiac output, heart rate, and SAP along with a marked increase in pulmonary and systemic vascular resistance is unknown. Seemingly, a large volume of blood is trapped peripheral to the heart in either the pulmonary vascular tree (increased central blood volume) and/or the

peripheral microcirculation. A "tourniquet" effect has been postulated in which postcapillary sphincter (venular) spasm predominates. In turn, venous return to the heart falls. Presumably this is due, at least in part, to a massive sympathetic outflow with intense sympathoadrenal hyperactivity. If so, the effect appears to be transient and the hemodynamic changes are not modified by pretreatment with alpha-adrenergic receptor antagonism (dibenzyline).[9] Increased vagal activity may well explain the transient bradycardia since the usual physiologic response to acute hypotension is a reflex tachycardia. Finally, alterations in vessel compliance (distensibility) of the systemic vascular bed, particularly the capacitance vessels (the large veins), may well account for much of the "missing" volume.

The hemodynamic response to volume therapy is as expected and clearly illustrates the pathologic problem: impaired tissue perfusion secondary to the sequestration of blood volume peripheral to the heart.

Earlier it was thought that the hepatosplanchnic circulation was particularly sensitive in the dog to endotoxemia so that massive entrapment of blood in the gut and liver resulted from hepatic venovasoconstriction. A recent report by Guntheroth and Kawabori[11] raises serious doubts about that view. Further, myocardial dysfunction might impair cardiac output. However, the prompt response to osmotically active volume therapy confirms an earlier observation[12] that the pump appears intact and, if provided with volume, can distribute that volume without the need for supplementary cardiotonic or inotropic amine drugs. Further, with the increase in circulatory volume achieved with dextran, hemodynamic normalcy was restored along with an improvement in the metabolic indices. Those data stand in sharp contrast to an earlier finding[9] in which the hemodynamic parameters were restored with a vasoactive amine drug (metaraminol) but the metabolic indices deteriorated even further. Thus, treatment of the animal in shock with agents other than ones producing volume expansion will have to achieve results at least equal to those observed with oncotic fluid therapy.

Finally, the changes in right atrial (central venous) pressure in the shocked animal which follow volume therapy confirm other reports[13] which seriously question the validity of that parameter as an index of volume sufficiency. On the other hand, PAWP more accurately assessed cardiac filling and output.

Do endorphin residues of beta lipotropin in hormone reinforce reproductive functions?

CHARLES D. KIMBALL, M.D.
Seattle, Washington

The beta-endorphin residue of pituitary beta-lipotropin hormone, which regulates utilization and storage of body fat, is several times more potent than morphine in raising pain tolerance. It also produces habituation and dependency behavior. Recently it was found to be present in amniotic fluid and to be a releaser of prolactin. It now appears that the placenta is a rich source of endorphins. These findings may open a new chapter in understanding molecular determinants of behavior patterns responsible for natural selection and survival of vertebrate species. Clinical application of basic information and new concepts relating endorphins to maternal behavior patterns and neonatal physiology is the purpose of this communication. A brief review of the literature, some data from [^{3}H]opiate-binding assays, observation of maternal performance, and reports of maternity patients' feelings and motivations suggesting that these hormone molecules mediate formation of affectional attitude, appetitive systems, and maternal behavior will be presented. (AM. J. OBSTET. GYNECOL. 134:127, 1979.)

If we ask Nature the right questions and listen to what Nature is trying to tell us—she will give us the right answers.

Louis Pasteur

MANY REPORTS have now established the fact that 61 tyrosine fragments of the 91 amino acid sequence constituting beta-lipotropin hormone (BLPH), known as enkephalin ($BLPH_{61-65}$) and β-endorphin ($BLPH_{61-91}$), are considerably more potent than morphine in increasing tolerance to pain[13, 29, 31, 31a] and will produce addiction and dependency behavior patterns in vertebrate creatures.[32, 33]

Other reports have reliably demonstrated that these ubiquitous opioid molecules (1) are evoked by physiologic stress in parallel with adrenocorticotropin (ACTH),[9] (2) stimulate release of prolactin hormone necessary for production of milk,[8, 19, 34] and (3) suppress hostility, irritability, and anxiety and induce affectional grooming behavior as will small doses of morphine.[7, 30, 35] All of these reactions are completely reversed by the opiate antagonist naloxone which will displace both endorphins and opium compounds at nerve cell receptor sites.

The discovery of enkephalin was first reported in December, 1975.[13] Subsequent reports during 1976 lead to interesting questions: What purpose in biologic evolution and selective survival is served by a natural hormone that produces lactation, affectional behavior, and addictive dependency? Is it possibly related to physiologic mother-neonate interdependency? Contemplation of these teleological questions prompted our efforts to investigate beta-endorphin molecules in reproductive behavior.

It seemed logical that the placenta, which is well known as a steroid and peptide hormone "factory,"[4, 5, 24] should also produce β-endorphin under the physiological challenge of labor. In January, 1977, we began trying to acquire (from The Salk Institute in La Jolla, California) information regarding radioimmunoassay reagents to measure β-endorphin in amniotic fluid and blood plasma of mothers and newborn. Subsequently, in September, 1977, we were greatly pleased and stimulated when Dr. Roger Guillemin of The Salk Institute with Dr. J. P. Gautray and his colleagues of Creteil, France, reported that β-endorphin, as we had anticipated, is evoked in amniotic fluid during labor.[6] It rises as much as twentyfold during difficult and prolonged labor and thus is an indicator of fetal distress. They also found that lowest assays in amnitoic fluid from cesarean births and considered the infant pituitary to be the source of beta endorphin.

Early in 1977, we began storing frozen amnitoic fluid

and plasma from umbilical cord and maternal blood. The samples were from unmedicated mothers during labor and shortly after birth. Most mothers who actively participate in normal physiologic labor tend to manifest high emotional elation and euphoria. We also collected frozen plasma samples of maternal blood before and soon after periods of breast-feeding to test for circulating endorphins. Small samples of colostrum and meconium were also collected and stored to be tested for the possible presence of endorphin-releasing enzymes.

Mothers (and a few participating fathers from whom plasma samples for endorphin assay were also collected) were graded on a maternal aptitude and performance scale similar to the Apgar score. Their subjective feelings and emotional attitudes were elicited at intervals during the first postpartum trimester. Most, but not all, of this small group of expectant parents had attended prenatal classes oriented to active participation in childbirth and breast-feeding.

In December, 1977, Dr. Henry Yamamura generously offered to assay the opioid molecules in our samples at his laboratory at the University of Arizona.

Methods

The[^{3}H]naloxone-binding assay[27, 28] is a sensitive and convenient method to measure opium receptor ligands in biologic fluids. Specific radioimmunoassay to identify human beta lipotropin[18] and alpha and beta endorphin[11, 25] were recently reported but antibody sera and labeled antigens are not yet available to us.[10, 10a] Enkephalin radioimmunoassay reagents are commercially available but rapid tissue enzyme degradation and the brief half life of the pentapeptides negate their use in this clinical study.

Observations of physiologic performance and behavior of mothers and infants were made. Maternal mood reactions and emotional impressions were elicited by semistructured interviews to be correlated later with endorphin assays.

Results

N. E. Pedigo and H. I. Yamamura have graciously made it possible for me to be the first to report that the placenta appears to be a rich source of natural endorphin opiates. Using [^{3}-H]naloxone binding they found that homogenized extracts of placenta from normal, unmedicated, term births will yield approximately 200 μg (60 nmoles) of opioid substance per gram of tissue. This material is assumed to be β-endorphin which is the most stable of the BLPH opioid residues.

Assays of our frozen plasma and amniotic fluid samples are in process. Results were not yet available at the time of this writing.

Comment

In the light of evidence available at present, several statements can be made with reasonable validity. Molecules that bind opioid receptors are generated by the placenta during physiologic labor. Physiologic stress and insulin-induced hypoglycemia elevate circulating BLPH,[18] ACTH,[9, 24] melanocyte-stimulating hormone,[4] prolactin,[33, 34] and endorphin opiates.[9] Presence or absence of endorphin opiates influences moods and feelings. Feelings modulate perception and thinking. Thinking controls behavior. To quote Barchas and colleagues,[2] of the Department of Psychiatry at Stanford, "There is compelling evidence that behavioral events alter neurochemical functions and that altered neurochemical functions can change behavior." β-Endorphin increases in amniotic fluid as much as twentyfold during parturition and may reflect fetal distress in prolonged and difficult labor.[6]

Opiates stimulate prolactin[8] and breast milk secretion, which motivate feeding and nurturing behavior.[5, 35] Prolactin is suppressed by naloxone.[34] Opiates also reduce hostility, irritability, and anxiety and induce affectional grooming behavior which naloxone reverses.[7, 35]

Perineal analgesia is usually present in the second and third stages of normal physiologic labor. The euphoria and high elation manifested by most women following physiologic birth of their infants are quite comparable to those evidenced by narcotics addicts following intravenous injection.[30, 35] Mothers experienced in breast-feeding report enjoyable mood and affectional feelings during nursing which some state are similar to their reactions to codeine and Percodan. The fact that affectional behavior is induced by endorphin and prolactin, both of which are antagonized by naloxone, implicates this combination of peptide hormones in the structural-functional modality[1, 12] of care-giving behavior, the mother-infant pair bond, and other affectional relationships.

This raises another question: Does our North American custom of promptly cutting the umbilical cord and removing the placenta following birth deprive mothers and infants of placental opioid molecules designed to induce interdependency of mothers and infants? Failure of this structural-functional hormone physiology at such a critical time in mother-newborn neural programming experience may result in reward frustration. It may also set autonomic patterns for paradoxical maternal apathy or antipathy observed experimentally in subhuman species[26] and in battering mothers who were deprived of normal neonatal imprinting experi-

ence.[15, 15a, 16] Inability to generate and respond to endorphin and prolactin may be the mechanism responsible for autistic intolerance to physical intimacy, psychosexual dysphoria, self-destructive depression, drug addiction, and the sociopathic alienation of disaffected youth, which has increased during the past two or three decades.[35] β-endorphin injections produce a remedial influence on mood and behavior of mental patients.[14, 17]

Recent reports indicate ACTH and prolactin will prevent onset of respiratory distress syndrome (RDS) and fatal hyaline membrane disease in premature infants born wih low lecithin/sphingomyelin ratios and with plasma prolactin levels below 200 ng/ml. Morrison[21, 22] in a double-blind study of 126 premature births stated that administration of 500 mg of hydrocortisone to mothers early in premature labor results in a significant decrease in RDS and infant mortality rates. Mendelson[20] reported that RDS did not occur in neonates with cord blood prolactin levels above 200 ng/ml but was present in 80% of 191 premature infants with cord blood prolactin levels below 200 ng/ml. Mendelson also pointed out that opiates stimulate prolactin and that RDS is extremely rare in premature infants born to heroin-addicted mothers. She suggested that prolactin is the natural trigger for surfactant synthesis in the fetal lung. It appears more probable to us, however, that the ACTH and β-endorphin molecules generated by the term placenta during active labor are responsible for elevation of fetal corticosterone, prolactin, and lung surfactants and act to prevent onset of RDS and hyaline membrane disease.

Returning to the question posed in the title of this paper, it is central dogma in biology that evolution and survival depend on nature's system of selecting the fittest to survive and propagate. It is a basic tenet of psychology that extinction of a behavioral pattern occurs if the reinforcing rewards fail to be provided. It is a matter of common agreement that sexual intercourse is a powerful reinforcer of affectional behavior and propagation and that opiates induce compulsive behavior and addiction. Given the fact that physiologic labor has been shown to generate significant amounts of placental opioids, it appears that placental endorphin is nature's payoff for physical stress and hard labors connected with making, bearing, and feeding new members of each oncoming generation. Thus, endorphins provide the emotional reward to reinforce biological behavior that contributes to propagation of the species and advances cultural evolution.[15, 16] This means to say that mothers normally enjoy conceiving, birthing, and feeding babies and normal fathers enjoy doing these with them.

We now postulate that endorphin molecules provide the physiologic rewards to reinforce maternal affect and compel nurturing behavior as well as motivate paternal dominance and protection of dependents in the family unit. In other words, it appears that biologic events beginning at puberty such as courtship, mating, birthing and feeding of young, and defense of dependents and territory will generate BLPH residues and create appetitive needs to repeat activities which supply endorphin ligands to satisfy natural opiate receptors. Placental endorphins generated during labor reward the mother's birthing effort, arouse her appetite for opiate receptor ligands, stimulate prolactin, and initiate feeding-nurturing behavior.

Deprivation and failure to achieve satisfaction of innate biologic appetites, which include endorphin rewards and sexual gratification, result in frustration and the development of compensatory substitutes, some of which may be sociopathic or self-destructive. For example, lacking the endorphin feedback that normally accompanies physiologic birth and stimulates lactation, some mothers tend to become depressed with postpartum "blues" or annoyed and irritated instead of rewarded while serving their infants' continuing and insatiable demands for food and attention. This frustration of affectional communications leads to more or less autistic behavior, the extreme examples of which are the asocial motherless monkeys, reported by Seay and colleagues,[26] that abused, rejected, and battered their firstborn infants. Other examples of compensatory mechanisms might include excessive eating, proneness to drug addiction, angry, rebellious countercultural behavior, or mental illness.[3, 17] The fact that β-endorphin injections are reported by Kline and associates[17] to be a spectacular remedy for profound depression and long-standing schizophrenia suggests that recurrent endorphin depletion or inability to generate proper endogenous opiate receptor ligands may be of etiologic significance.

Our hypothesis that endorphins act as multifaceted biologic behavior regulators doubtless upset many deeply entrenched ideas of human behavior theory and engender vigorous or even violent opposition, as, for example, the Wilson-Lewontin[36] controversy over sociobiology. Despite the tendency to cling to long-cherished beliefs, the truth will eventually prevail. Micromeasurement of these neuroregulators of survival behavior mechanisms is now possible and sooner or later will provide a factual molecular foundation for a structural-functional science of behavior.

The growing trend toward the age-old "do it yourself" method of physiologic birth and infant feeding advocated by the Childbirth Education Association and

LaLeche League reflects the innate wisdom of women in matters of reproductive biology and family survival. Newborn infant brain circuits require specific affectional input to program neurohypophyseal production of endorphin hormones necessary for basic security and independent identity.

To conclude that opioid residues of beta-lipotropin hormone do not exert significant and compelling influence on reproductive and survival functions would deny the self-evident logic propounded in Darwin's *Origin of the Species* and Teilhard deChardin's *Phenomenon of Man*[23] as well as the integrated evidence from molecular biology and behavioral science.

Discussion

DR. EUGENE C. SANDBERG, Stanford, California: What I heard in Dr. Kimball's presentation is that he has initiated a project (which he hopes to complete) and he is excited about the anticipated results. He justifies both his enthusiasm and his pursuit of the project by citing results from recent research. Additionally, he speculates on the potential that continued research in the subject area discussed will provide an understanding of the basic neurochemical mechanism responsible for reproductive behavior. In formulating his thesis he has taken liberties with reported observations and conclusions, has exaggerated the profundity of certain findings, has made a number of unwarranted assumptions, and has offered what appear to be a number of extravagant speculations. It might be superficially justifiable and ephemerally entertaining to question, contest, or attack these areas of vulnerability. Such an approach, however, would serve only to generate a nonproductive tempest and would ignore the virtues of the presentation and the importance of the basic message which, oddly enough, at least as I perceive it, is not to be found in the presentation. Rather than chase the decoys (the endorphins and the enkephalins), I would like to offer my interpretation of the basis of and the motivation for Dr. Kimball's presentation and point out what I feel to be his important, but regularly neglected, contribution to the advancement of obstetric care. Some background information, undoubtedly presupposed as evident by Dr. Kimball because he has thought it and said it so frequently and for so long, provides the missing links that place today's presentation in perspective.

Broadly defined, ethology is the study of animal behavior. One aspect of ethology deals with the biologic forces that control reproductive behavior. This aspect includes maternal behavior toward the offspring that accentuates the potential for successful reproductive behavior by the offspring in turn, thus enhancing the prospects for perpetuation of the species. Dr. Kimball is devoted to this aspect of ethology and twice before, in 1966[1] and 1974,[2] presented to our Society eclectic data from this discipline. At one time, the concept prevailed that all reproductive behavior was genetically preprogrammed, instinctive, and not substantially modified by environment or experience. In his presentation in 1966, Dr. Kimball reviewed results of research demonstrating the importance of "imprinting" on the newborn animal's subsequent behavior, including that related to reproduction. Receipt by the infant of affection, security, warmth, protection, and fulfillment of needs by the mother (i.e., what most of us would term "appropriate maternal nurturing") was vital in establishing reproductively effective behavior in the offspring. For example, newly hatched goslings, "imprinted" by a human acting in the maternal role, followed and responded to the surrogate mother as other goslings did their natural mothers. The birds subsequently courted the human and failed to mate with their own kind. In other experiments, monkeys deprived of all maternal contact following birth subsequently could not form appropriate or typical relationships with other monkeys and failed or refused to mate. When reproduction was forced upon them by artificial insemination, an experiment suggested to the researcher by Dr. Kimball, the "motherless monkeys" totally ignored their infants from birth and rejected and even severely abused them when the infants sought maternal closeness. Many survived only through intervention by the investigator. In essence, behavior necessary for perpetuation of the species failed to develop in mother nurture–deprived animals, at least with the initial pregnancy. In humans, sociopathic behavior and emotional disturbances of various types, as well as subsequent abusive treatment of their own young, have been commonly noted in individuals deprived of effective maternal nurturing. A dozen years ago, Dr. Kimball asked the members of this society and fellow obstetricians everywhere to recognize these findings, to appraise the attitude and character of their obstetric patients, and to attempt to anticipate instances of lack of appropriate maternal nurturing in the hope that this requirement could somehow be afforded to the newborn infant by natural or surrogate means. This represented one of the earliest appeals to clinicians to bring the fruits of ethological research to clinical practice and to initiate preventive measures against the development of behavioral problems and emotional illness.

In his presentation 4 years ago, Dr. Kimball expanded on these points and added infantile autism and childhood depression and schizophrenia to the list of conditions inducible by the lack of maternal nurture. Most importantly, Dr. Kimball described his own practical attempt to prevent behavioral illness. He described the establishment of a program in Seattle in which inexperienced, inept, frightened, and potentially dysadaptive parents could be informed of the necessity for maternal nurturing and given adequate information and support to effectively provide this to their offspring. Because of the avant garde nature of the program and its tremendous potential, it would be interesting and important to learn of its results. Unfortunately, these have not yet been made available.

It is apparent that Dr. Kimball is desperately desirous of finding a molecular foundation and a "hard science" explanation for the "soft science" observations described to date in ethology and the other behavioral disciplines. In 1974, he looked hopefully to the experimentally popular neurotransmitters, dopamine and norepinephrine, for that foundation. In today's presentation, he looks hopefully to the hottest new items in neurochemical research, the endorphins and the enkephalins, for that support. Despite the certainty of their importance, most of which is yet to be determined, it seems unlikely to me that the endogenous opioids are as vital and basic to behavior and its evolutionary transmission as Dr. Kimball dreams them to be.

Regardless, I am grateful to him for drawing our attention to the opioids and for stimulating our minds with his enthusiasm. And while he pursues his laboratory research, I am hopeful that he will not forego his crusade to inform clinicians of the essentiality of maternal nurturing. I am hopeful that obstetricians will soon recognize an additional responsibility to the infant beyond the simple provision of a safe delivery. I am additionally hopeful that obstetricians will soon seek out pediatricians, child psychiatrists, psychologists, social workers, and others sensing a similar responsibility and establish programs in parenting and preventive psychiatry. Programs such as that outlined previously by Dr. Kimball and that recently described so eloquently in the Jacobi Lecture by Kempe,[3] a pediatrician working in the area of child abuse, are excellent examples. And last, as these things come to pass, and I feel they will, I hope that Dr. Kimball's efforts and foresight will not go unrecognized, unappreciated, and unrewarded.

DR. JAMES C. CAILLOUETTE, Pasadena, California. I would feel remiss if I did not congratulate Dr. Kimball on this significant contribution. He has made persistent and repeated efforts to educate this society, and our specialty, on that most important subject, "behavior." In 1966, he introduced the word "ethology" to this group with his paper entitled, "Ethology in clinical obstetrics." I reintroduced the subject to this group in 1969 with my paper, "Ethology in the teaching of obstetrics and gynecology." Reassuring for Dr. Kimball, and for me, was the fact that in 1973 that most cherished scientific award, the Nobel Prize, was awarded to three ethologists: Konrad Lorenz, Nikolaas Tinbergen, and Karl von Frisch.

Until recently, nonverbal communication between members of the same species and members of different species was not understood and therefore skepticism persisted.

Today, in my opinion, Dr. Kimball has helped to break the code. He has told us about beta-endorphin residues and their effect on behavior—as well as their being a possible signal of fetal distress. Incidentally, I believe it is one of the current theories of the mechanism of acupuncture.

I would like to support Dr. Kimball's good work by adding yet another dimension to the subject of behavior. Another new word is "pheromone"—defined as "a substance, secreted to the outside of the body and perceived (as by smell) by another individual of the same or different species, releasing a specific reaction to behavior in the percipient."

In my opinion, the understanding of, and the ability to prudently control, behavior is what civilization is all about.

DR. KIMBALL (Closing). I was disappointed that no attention was paid to RDS, which I think at the moment is the most important aspect of our investigation of these molecules in maternal and cord blood which we think evoke prolactin. The future will, of course, tell the story. The circumstantial evidence is compelling. The factual data will be forthcoming. In regards to Dr. Sandberg's doubts regarding qualifications of this investigation, I am just really getting started at it. I hope to live long enough to see it culminated in some degree. I do think that within the next year or so we can determine whether, in fact, endorphin is the releaser for prolactin. Indeed, these molecules may be the mediator of a great many so-called survival behavior patterns—not only in our species but in the mothers of all other species which require reinforcing. Animals will not do anything without a reward, a payoff. When Dr. C. H. Li of the University of California at Berkeley began studying endorphins, he investigated the beta-lipotropin molecule in camels, because camels will go out and walk around the desert for days and their reward seems to be just going out and walking around on the desert. This suggested there must be something making them feel good about it—like joggers feel so good when they jog and some joggers get really high on jogging. It has been established and definitely established that acupuncture and the so-called transcutaneous electrical stimulator does increase endorphin in spinal fluid and will relieve intractable pain of cancer much better than morphine. This has been done at the University of California, San Francisco, in the Department of Neurosurgery. There is no question about the fact that an opioid molecule exists. We believe we have found it in the placenta, in relatively large amounts. We will see how it turns out.

Severe dysplasia and carcinoma in situ of the vagina

JOSEPH A. OLIVER, JR., M.D.
Pasadena, California

Papanicolaou smears for early detection of carcinoma in situ of the cervix has been a well-recognized method of screening patients for over 30 years. The necessity for Papanicolaou smears following hysterectomy, especially for benign disease, has been a controversial subject. Twenty-two cases of carcinoma in situ of the vagina, over a period of 18 years, at the Huntington Memorial Hospital in Pasadena, California, are presented. Ninety-five percent of the lesions were first suspected by use of the Papanicolaou smears. Approximately half of previous hysterectomies were performed for benign disease. The various methods of treatment employed and the complications in these patients are discussed. (AM. J. OBSTET. GYNECOL. 134:133, 1979.)

FOLLOWING HYSTERECTOMY, whether vaginal or abdominal, in situ carcinoma of the vagina is rarely seen, yet when it exists it must be diagnosed. Twenty-two cases were seen from 1960 through 1977. Abnormal Papanicolaou smears led to early detection of this disease. Treatment varied widely, and the methods of treatment, results, complications, and follow-up will be discussed. The use of iodine stain to localize the lesion and colposcopy in determining the extent of the disease prior to excision has been very helpful.

Because of the great similarity in abnormal vaginal and cervical cells, Papanicolaou smear for early detection of intraepithelial neoplasia of the vagina is a valuable method of detection of intraepithelial disease of the vagina.[1]

Carcinoma in situ of the vagina was first described in the American literature in 1952 by Graham and Meigs.[2] Moran and Robinson[3] reported a case in the Spanish literature in 1948. A malignant lesion of the vagina was first described by Cruveilhier in 1827. Early vaginal lesions by gross examination were recognized and reported by Mackenrodt[4] in 1896. Merrill and Bender[5] and others have pointed out the similarity between the natural history of dysplasia and carcinoma in situ of the cervix and vagina. In the 1940s and 1950s Hummer and associates[1] reported from the Mayo Clinic a series of unexpected abnormal Papanicolaou smears in a group of patients who, months or years earlier, had undergone hysterectomy for carcinoma in situ of the cervix. The prognosis in the intraepithelial stage is generally good, similar to that of carcinoma of the cervix, as pointed out by Hummer and associates[1] and Rutledge and colleagues.[6]

Presented by invitation at the Forty-fifth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Gleneden Beach, Oregon, September 26-30, 1978.

Reprint requests: Dr. Joseph A. Oliver, Jr., 65 North Madison Ave., Pasadena, California 91101.

Material and methods

Twenty patients with a diagnosis of carcinoma in situ of the vagina from 1960 through 1977 and two patients with severe dysplasia of the vagina were included in this series. Patients with invasive carcinoma of the cervix and vulva were excluded. There were no patients exposed to diethylstilbestrol in utero.

Results of treatment

Twenty-one of 22 cases were squamous in origin. One lesion was described as adenocarcinoma in situ, which occurred 7 years after total abdominal hysterectomy and bilateral salpingo-oophorectomy for adenomatous hyperplasia. These patients have been followed up for 6 months to 18 years. Twenty-one of 22 patients are still alive. Twenty of 22 patients are free of disease. One patient developed recurrent squamous cell carcinoma 4 years after vaginectomy and is alive with disease following pelvic radiation.

Twenty-one of 22 cases (or 95%) were suspected as the result of abnormal Papanicolaou smears obtained on routine pelvic examinations. Iodine stain was utilized in 17 of the patients and a nonstaining area with positive lesions was found in 16 patients (94%). Fourteen patients (64%) had a solitary lesion of the upper vagina. Eight patients (36%) had multifocal lesion involving primarily the upper vagina; in three patients the lesion involved the upper and lower vagina. Nineteen patients had undergone previous hysterectomy, 11 for benign disease and eight for carcinoma in situ of the cervix. Three patients had negative cone biopsy

0002-9378/79/100133+05$00.50/0 © 1979 The C. V. Mosby Co.

following abnormal Papanicolaou smears. Two of the three lesions were severe dysplasia; one was carcinoma in situ of the vagina.

Surgery.

Simple excision. Surgery was performed in 17 of 22 patients. Simple excision biopsy for intraepithelial vaginal disease was utilized in 14 of the patients. Eleven patients were sexually active and experienced no dyspareunia. No patients developed stress incontinence from vaginal stenosis. Three of these patients had abnormal Papanicolaou smears, with negative cone biopsies of the cervix. The vaginal lesion was identified with iodine stain and colposcopy.

Vaginectomy. Two patients with large-area lesions involving the entire upper third of the vagina underwent vaginectomy; both have had recurrence of disease. One carcinoma in situ occurred one year after excision biopsy. Vaginectomy and split-thickness skin graft were performed to remove the lesion and maintain sexual function. The other patient developed recurrence 4 years following vaginectomy, and the recurrence was manifested by a pelvic mass which proved at laparotomy to be squamous cell carcinoma. She has had good response to radiation therapy and is alive with disease 1 year following therapy.

Pelvic exenteration. One patient underwent pelvic exenteration 9 years after treatment with radiation and hysterectomy for carcinoma in situ of the cervix. Results of a punch biopsy of a vaginal lesion were reported as invasive disease. The vaginal lesion at the time of exenteration showed only carcinoma in situ of the vagina. This patient died on the fourth postoperative day of pulmonary complications.

Radiation therapy. Four of the 22 patients were treated with intravaginal radiation therapy. Two patients developed vaginal shortening and stenosis, followed by dyspareunia, and have since been treated with estrogen cream and vaginal dilators, with acceptable sexual function. Four patients have remained free of disease.

Chemotherapy. Topical 5-fluorouracil was utilized in one patient, a treatment described by Woodruff and colleagues.[7] This patient developed an abnormal Papanicolaou smear, with a "blush" lesion proved by biopsy to be carcinoma in situ of the vagina. She refused surgical excision of these areas and is free of disease 4 years following topical chemotherapy; Papanicolaou smears have remained negative.

Comment

Many gynecologists and internists feel that Papanicolaou smears are no longer indicated following hysterectomy, especially following hysterectomy for benign disease.[1, 8, 9] Hummer and colleagues[1] pointed out that the patient with an abnormal Papanicolaou smear rarely has any complaints with these lesions. This finding was substantiated in 21 of the 22 cases. Nine of the 22 patients had visible lesions which were noted with careful examination and iodine stains after abnormal Papanicolaou smears. These lesions have been described as "blush" lesions by Gray and Christopherson,[10] who found, by biopsy, that 80% of them were preinvasive.

The average age of patients with carcinoma in situ of the vagina in this series was 53.5 years, which is similar to the findings of Hummer and co-workers.[1] Recent studies in the United States reveal that approximately 0.4% of female genital tract lesions are preinvasive lesions of the vaginal tract.[11] Most authors feel that previous carcinoma in situ of the cervix predisposes the patient to carcinoma in situ of the vagina, and Scales and Hartman[12] feel this multicentric theory is probably true, since the epithelium of the vagina and cervix originates from the urogenital sinus. Carcinoma in situ of the cervix preceded the vaginal lesion in eight of 22 cases (39%) and occurred from 6 months to 10 years after the original surgery. It is not uncommon to find carcinoma in situ of the vagina several years after a hysterectomy for benign disease or after carcinoma in situ of the cervix. Rutledge[3] has reported at least seven cases in which this has occurred up to 22 years following primary surgery. Rutledge feels that patients who wish to maintain sexual activity should have local excision and skin grafts when indicated. Brown and colleagues[13] have found recurrence in patients treated by local radium therapy and feel this is due to "cold spots" caused by rugae of the vagina, thus leading to the opinion that partial vaginectomy is the treatment of choice. The multiple angles created by vaginal rugae make colposcopic evaluation of the vaginal lesion more difficult than that of the smooth surface of the cervix. Preoperative treatment with estrogen creams has been advocated by Gray and Christopherson[10] in the postmenopausal patient. Topical cream reduces atrophic changes, makes the intraepithelial lesion more apparent, and increases vaginal mucosal elasticity.[14]

The problem with scarring and stenosis of the vagina following radiation is not new and certainly not confined to this disease. However, the patients who have radiation as a means of treatment should receive estrogen cream, as well as vaginal dilatation, to prevent stenosis, scarring, and loss of sexual function.[8]

Colposcopy has been very helpful in evaluation of cervical lesions and of some value in vaginal lesions but multiple refractory angles of vaginal rugae make evaluation of invasive vaginal carcinoma inaccurate.

• Other methods of treatment, such as topical 5-fluorouracil cream, cryosurgery, and laser surgery, should be used only in patients who are poor surgical risks or refuse surgery. The importance of total excision of these vaginal lesions cannot be overemphasized for by this method of total removal the depth and extent of penetration of the lesion can be adequately evaluated and inadequate treatment of invasive vaginal disease can be avoided.

Discussion

Dr. Edward C. Hill, San Francisco, California. It is noteworthy that all but three of the patients in Dr. Oliver's series had previously undergone total abdominal hysterectomy. That almost half of the hysterectomies were done for neoplastic disease of the cervix is not surprising for this places the patient at risk for the subsequent development, or at least the finding, of carcinoma in situ of the vagina. It is quite extraordinary to find carcinoma in situ of the vagina in a patient who has had a hysterectomy for a disease which was ostensibly benign. This raises the question of the need for routine cytologic examination of the vagina in such patients, and Dr. Oliver has recommended that this be done, presumably on an annual basis.

At the University of California, San Francisco, the ratio of vaginal to cervical cancer has been 1:50. Others have found a ratio as high as 1:24. If the risk of cervical cancer in the general female population is approximately 1%, then it can be presumed that the risk of vaginal cancer, at the most, is about 1:2,500.

It has been established that about 750,000 hysterectomies are performed annually in the United States. If 25% of these are done for neoplastic disease, then 562,500 patients per year have hysterectomies for benign disease. At $10.00 per cytologic examination, it would cost a minimum of $25,000 to detect a single case of carcinoma of the vagina by routine cytologic examination in this population. Is this a reasonable cost-benefit ratio?

One must also ask what led to the cytologic examination of the patients in Dr. Oliver's series who had previously experienced hysterectomy for benign disease. He has indicated that six of the 11 patients had visible lesions. Was the smear obtained in each of these cases because of the lesion? It is not clear from the paper what these lesions looked like. Were they the so-called "blush" lesions which he mentioned, or were they areas of leukoplakia? Were they noted by someone whose eye had been trained by colposcopy?

The three patients in this series who had intact uteri were all 30 years of age or younger and cone biopsy of the cervix was done in all because of abnormal cytologic smear. In each instance the cervical cone specimen demonstrated mild dysplasia while the vaginal lesion presented a more marked degree of intraepithelial neoplasia. It appears that these three patients represented cases in which a field of dysplasia was found with the more severe form of the process in the adjacent vagina rather than in the cervix.

All but one of the patients had involvement of the upper third of the vagina. Does this mean that there is some relationship between the development of vaginal neoplasia and the role of the müllerian duct epithelium in the embryologic development of the vagina? Experience with cervical intraepithelial neoplasia and the concept of the expanded transformation zone in diethylstilbestrol-exposed female subjects would lead us to believe so.

Purely out of curiosity, I thought it would be interesting to compare the essayist's series of patients with the experience at the University of California, San Francisco. A review of the 10 years from 1968 through 1977 produced 22 patients with carcinoma in situ of the vagina, ranging in age from 29 to 77 years with an average age of 56.7 years. Twelve of these had prior hysterectomy, nine of which were for malignant disease, primarily of the cervix. In the three patients who had hysterectomy for benign disease, one had carcinoma in situ of the vulva 2 years previously, so she was at risk, and another had worn a Gellhorn pessary for 10 years and had a visible lesion. Of the 10 patients who had not

had prior hysterectomy, 80% had received radiation therapy, primarily for carcinoma of the cervix, from 8 to 29 years prior to the diagnosis of vaginal carcinoma in situ. In the two patients who had not received radiation therapy, one had been treated for carcinoma in situ of the vulva and the other had been receiving immunosuppressive therapy for a kidney transplant and had also been treated for carcinoma in situ of the cervix as well as the vulva. So only two of the 22 patients had carcinoma in situ of the vagina without apparent relationship to neoplasia elsewhere in the reproductive tract and one of these was attributed to the use of a vaginal pessary for many years.

Although our experience differs from Dr. Oliver's, I agree with his conclusions except for his advocation of routine cytologic examinations of the vagina in women who have had hysterectomy for benign disease. An occasional smear, say once every 5 years, ought to suffice. Carcinoma of the vagina in this selected group of patients must be very rare indeed.

DR. JAMES F. NOLAN, Los Angeles, California. Recently we made a study similar to Dr. Oliver's. Our findings were remarkably similar to his, with some minor exceptions which may be worth discussion.

We found some 36 patients who were diagnosed as having vaginal carcinoma in situ in a 22 year period (1955 to 1977). Only four of these patients had no previous gynecologic treatment. Of the 32 treated previously, only six were reported to have benign disease. The remainder had been treated by surgery or radiation therapy for carcinoma of the cervix, either in situ or invasive. The vaginal carcinoma in situ was diagnosed from 1 to 19 years after the original procedure, with an equal distribution of patients before and after 5 years of follow-up. The cause of these new preinvasive lesions remains moot, but continued surveillance in treated patients seems indicated.

As far as treatment of the carcinoma in situ is concerned, there may be some divergence of opinion. Of course, the end results with different modalities are similar and hover at about a 100% success rate. We treated the majority of our patients with local radium implants but were completely successful with all methods used. One patient who received radium developed cystitis and one developed proctitis—both controlled with conservative measures. Previously both had been treated for carcinoma of the cervix with full radiation therapy. One would think the problem of vaginal rugae should be overcome by packing and the fact that gamma radiation doses would not be significantly lowered within a few millimeters of the surface dose. As Dr. Oliver pointed out, the problem of postradiation atresia in sexually active individuals can be countered by measures similar to those used to maintain vaginal patency in the postoperative patients.

At least local radiation treatment is simpler than vaginectomy and was equally effective in our experience.

DR. LEON P. FOX, San Jose, California. Dr. Oliver deserves credit for championing the routine use of the Papanicolaou smear in patients following hysterectomy. We have been doing this in our office since we pioneered cytologic screening in our area in 1952. We have had a similar experience of identifying an occasional malignancy and several cases of dysplasia of the vagina. The numbers are small, but for the person who has the lesions it is a procedure of 100% value. The hysterectomized patient derives several advantages from the smear. It detects disease processes, indicates estrogen levels, and is one of the best incentives for patients to have routine checkups. Misinformed internists, surgeons, and many of our own colleagues are doing an injustice to these patients when they withhold this low-cost valuable service from them.

DR. LEO LAGASSE, Los Angeles, California. We have recently reviewed our experience in 12 patients treated with intravaginal 5-fluorouracil for carcinoma in situ of the vagina. All 12 of these patients responded completely after one to three 2 week periods of therapy. Three patients had recurrences 18 months to 3 years after treatment and all responded to another course of therapy. All were left with normal vaginas afterward. The treatment is very well tolerated. A few patients experienced burning of the vulva or urethra, which was prevented by a barrier-type ointment applied to the vulva before insertion of the 5-fluorouracil cream. It must be emphasized that very careful examination of the vagina with multiple biopsies is necessary to rule out invasive cancer with certainty in these patients. There appears to be a place for 5-fluorouracil in the treatment of vaginal carcinoma in situ. I would suggest it to you as an alternative to surgery or radiation.

DR. WILSON FOOTER, Oakland, California. I have found that approximately one third of the patients that I have seen with this condition have had radiation previously for various conditions, usually of the cervix. One had, as a child, a malignancy of the hip and was given radiation. Approximately one third had previous hysterectomy for a benign condition; the remainder, for malignancy The "blush" type of lesion was found in one patient at approximately 60 years of age. With manipulation there was a little bleeding from it but that was not one of her symptoms. This lesion should be excised, with a wide margin around the lesion, which can be demarcated colposcopically both in the office and by the operating microscope in surgery with Lugol's solution. We use Lugol's solution first and then toluidine blue. We utilize wide margins around and deep into the lesion. There has been no evidence of recurrence in the patient described, who was treated in 1971. She was also treated with dichloroacetic acid, which I have used on a number of cases. If the lesion is not at the apex but down inside the vagina, so that it is not involved with the previous scar from a hysterectomy, we can usually rely upon dichloroacetic acid, as well as excision or 5-fluorouracil to eliminate the condition. However, I have excised those that are at the

apex and those that go out into a dimpling at the side; where there was any shortening of the vagina, a split-thickness graft was utilized. However, in most, the extent of the lesion is such that the vagina is not very much shortened. It has been mainly those having this condition after radiation therapy who had enough shortening that the split-thickness graft was helpful.

DR. EDWIN T. MACCAMY, Seattle, Washington. I would like to ask Dr. Oliver if he has any special technique for obtaining the Papanicolaou smear. Does he just take it across the vaginal vault, as we would with the cervix still present? Apropos of Hill's comment that perhaps a Papanicolaou smear is not needed more often than every 5 years, I would like to describe a particular case to illustrate how long this disease can go on. A patient with a positive Papanicolaou smear, who was treated by cervical conization, had a negative tissue report. She then underwent hysterectomy and the hysterectomy specimen was negative. The general surgeon retired, and she had no further examination for 7 years. She then went to an internist who obtained a Papanicolaou smear, and again it was positive. She had carcinoma in situ of the vagina—a very diffuse carcinoma; still, it was only in situ after at least 7 years.

DR. BOYD C. QUINT, Seattle, Washington. Dr. Oliver mentioned that none of his patients were diethylstilbestrol-exposed infants. Dr. Hill alluded to this as a potential problem. I would just like to underscore that a little. Dr. Staphl, from Marquette University, has pointed out that he is very concerned about the possibility of diethylstilbestrol-exposed babies, the oldest of whom are now something like 27 years old, eventually developing squamous cell carcinoma in the widened transformation zone they have. We may well be sitting on a "powder keg" with these four million or more such exposed young ladies. Unfortunately, those of you who perform colposcopy are well aware of the fact that the usual colposcopic criteria of mosaicism and punctation are of no value in the diethylstilbestrol-exposed subjects—they all have these in the transformation zone and thus must be evaluated by Papanicolaou smear.

DR. OLIVER (Closing). One of the questions that Dr. Hill asked was what led to the Papanicolaou smear? This was just done on a routine yearly basis when the patient came in for her annual examination. Dr. MacCamy asked about technique: We just scrape the vagina as we do the cervix and there is no special technique involved.

Information for authors

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

Does adoption affect subsequent fertility?

EMMET J. LAMB, M.D.
SUE LEURGANS, PH.D.
Stanford, California

A hypothesis derived from the old wives' tale that adoption increases subsequent fertility was tested by analysis of follow-up data obtained from 895 couples who were "at risk" of pregnancy and of adoption after they had registered in the Stanford Infertility Clinic between 1963 and 1977. Of the 767 couples who did not adopt, 329 later conceived; of the 128 who did adopt, 41 later conceived. Simple comparison of the percentages or, indeed, of the life tables suggests reduced fertility after adoption. However, this is probably a spurious effect related to a number of factors which differ between two groups. These differences were controlled in the statistical analysis by methods which take into account the length of time each couple was at risk of either conception or adoption and the presence or absence of explanatory variables. The relative risk of conception estimated by the Cox model was not significantly different from 1 and the Mantel-Haenszel statistic ($m = -0.208$) indicates no significant difference in subsequent conception rates between adoptive and not-adoptive couples. The same methods were used to control for seven covariates, including age and duration of infertility, which could affect conception rates. In each instance, the estimate of relative risk of conception for adoptive versus not-adoptive couples was not significantly different from 1. Therefore, our data do not support the hypothesis that adoption affects subsequent fertility. (AM. J. OBSTET. GYNECOL. 134:138, 1979.)

EVEN THOUGH THE NUMBERS of babies available for adoption have been reduced in recent years by marked changes in society's attitudes toward contraception, abortion, and single parenthood, about 150,000 babies are adopted each year in the United States. Quite a few adoptive parents and at least some of their physicians hope that the adopted child will serve as a "fertility charm." The concept that adoption may be a cure for infertility is prevalent not only among the laity but even in medical circles.

In this study data from a large sample of infertile couples, studied and followed up in a uniform manner, have been analyzed using modern statistical methods in an attempt to answer the question: Does adoption affect subsequent fertility?

Methods

Data collection and definitions. Couples who registered in the Stanford Infertility Clinic between January 1, 1963, and the closing date of this study, December 31, 1976, form the study group. The following were excluded: those who were seen for one-visit consultation, those lost to follow-up immediately after registration, and those who were known not to be "at risk" of conception at the time of registration because of an existing, but undiagnosed, pregnancy or because of known factors which rendered them completely sterile. The tests included in the infertility investigation and the methods for data collection and tabulation are described in a previous paper.[6] Information about adoption, pregnancy, contraception, divorce, etc., was obtained from couples through follow-up visits or letters.

Until they had actually adopted, a couple was considered in the not-adoptive group. Thereafter, they were included in the adoptive group. Only first adoptions or conceptions following registration were considered. Couples were defined as adoptive only if the adoption occurred between registration and withdrawal from follow-up for any reason. Those who adopted before registration are included in the not-adoptive group. Routine follow-up procedures cease when it is learned that a couple has conceived or has withdrawn permanently from the risk of pregnancy by contraception, sterilization, divorce, etc. Therefore, our data are incomplete about adoption subsequent to a pregnancy or after sterilization procedures including hysterectomy.

Table I. Distribution of pregnancies among adoptive and not-adoptive couples in five studies. An estimated risk ratio less than 1 indicates that couples who adopted have a lower risk of pregnancy

Study	Year	No. of couples				Estimated risk ratio	Chi-square value
		Pregnant		Not pregnant			
		A. Adoptive	B. Not-adoptive	C. Adoptive	D. Not-adoptive		
Rock et al.[11]	1965	57	40	192	73	0.65	6.2*
Weir and Weir[12]	1966	32	44	165	197	0.89	0.3
Humphrey and McKenzie[3]	1967	7	76	52	81	0.25	24.2†
Arronet et al.[1]	1974	26	264	107	136	0.30	86.8†
Present study		41	329	87	438	0.75	5.3*

*$p < 0.05$; for 1 degree of freedom χ^2 ($p = 0.05$) = 3.8.
†$p < 0.01$; for 1 degree of freedom χ^2 ($p = 0.01$) = 6.6.

Table II. Distribution of conceptions and other events between adoptive and not-adoptive couples

	Status at last contact				Total
	Pregnant	Known not pregnant at close of study	Withdrawn from risk of pregnancy	Lost to follow-up	
Adoptive	41	44	27	16	128
Not-adoptive	329	180	199	59	767
Total	370	224	226	75	895

Such cases are included in the not-adoptive group and considered withdrawn from the study before adoption. These restrictions lead to an underestimation of adoption rates but do not affect calculation of conception rates.

The time interval from registration until each event (conception, adoption, loss to follow-up, withdrawal from the risk of conception) was calculated. The interval to adoption was determined by the arrival of the adopted child in the home rather than by the date of application for adoption. On the other hand, the interval to conception was determined by the last menstrual period, not by the date of delivery. The interval to withdrawal from the study because the couple was found to have a condition which made conception impossible, e.g., azoospermia or complete tubal occlusion, was determined by the date of diagnosis.

Whether the explanatory variable listed in Table III was present or absent was determined at the time of registration with the exception of therapy which was coded at the end of the follow-up.

The relevant medical literature of the past 20 years was reviewed and reports were selected which provided sufficient data for construction of a 2 by 2 contingency table. The estimated relative risk of conception was calculated using the formula $(A/A + C) \div (B/B + D)$ where A, B, C, and D are as defined in Table I. A chi-square test of independence was done for each row of the table with no correction for continuity.

Statistical methods. With the use of the intervals between registration and each of the ensuing events, life tables for the various groups were calculated with computer programs. In these calculations the three censoring events, loss to follow-up, withdrawal because of sterility, and survival to the close of the study, are handled in a similar fashion. The life tables were calculated using the formulas on pages 464 and 477 of Kaplan and Meier.[5] The overall significance test statistic M was calculated by the formulas on page 734 of Mantel and Haenszel[9] and page 79 of Hyde.[4] The hazard function and estimate of relative risk were calculated by the method on page 189 of Cox.[2] Analysis of the effect of the covariates listed in Table III was by the global significance test on page 191 of Cox. A more complete exposition for the statistician of the methods used in this study is in preparation.[8]

Results

Of 1,201 couples who registered in the clinic during the time of this study, 76 were known at registration to be not at risk of pregnancy either because, in 58, an undiagnosed pregnancy existed or because, in 18, an untreatable condition which rendered the couple sterile was known. An additional 232 patients were not followed up beyond the day of registration because they were seen for consultation only or were immediately lost to follow-up. Of the 895 couples remaining in the study, 370 (41%) did conceive and 525 did

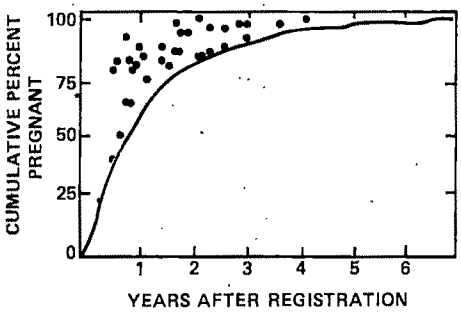

Fig. 1. Interval between registration and conception for 370 couples who conceived. Points which indicate couples who had adopted and conceived are plotted at a level on the abscissa corresponding to that couple's place on the curve. Thus, the horizontal distance between a point and the curve is the interval between adoption and conception.

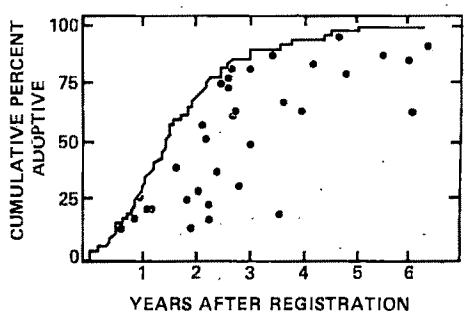

Fig. 2. Interval between registration and adoption for 128 couples who adopted. Points which indicate couples who had adopted and conceived are plotted as in Fig. 1. The horizontal distance between a point and the curve is the interval between adoption and conception.

not. At some time after registration and before conceiving 128 (14%) adopted. Of these adoptive couples 41 (32%) subsequently conceived. According to the chi-square test of independence, the estimated risk ratio 0.75 (adoptive/not adoptive) is significantly different ($p < 0.05$) from unity (Table I). Results of previous studies of the question of the effect of adoption on fertility are also listed in Table I.[1, 3, 11, 12]

The numbers of those in the study who were observed until the closing date, withdrawn because of sterility, etc., or lost to follow-up are listed in Table II.

The interval between registration and conception for the 370 couples who conceived is shown in Fig. 1. The median interval to conception was 0.81 years. The interval between registration and adoption for the 128 adoptive couples is shown in Fig. 2. The median interval to adoption was 1.40 years. The intervals between adoption and conception for couples who adopted and later conceived are also illustrated in Figs. 1 and 2. The median interval was 1.0 years; the range, 0.1 to 3.6 years; the mean, 1.48 years; and the standard deviation, 1.86 years.

Life-table estimates of the proportion of couples who had conceived at intervals after registration are shown in Fig. 3. We estimate that had all not-adoptive couples been observed for 5 years, 69% would have conceived. The corresponding points are 35% for adoptive couples and 63% for all couples. The Mantel-Haenszel statistic $M = -0.208$ does not differ significantly from 0, indicating that the relative risk of conception (adoptive/not-adoptive) does not differ significantly from 1.

The effect on the relative risk of conception for adoptive versus not-adoptive couples and for couples with seven explanatory variables is shown in Table III. Using life-table methods of analysis we found a significant difference in conception rates between the

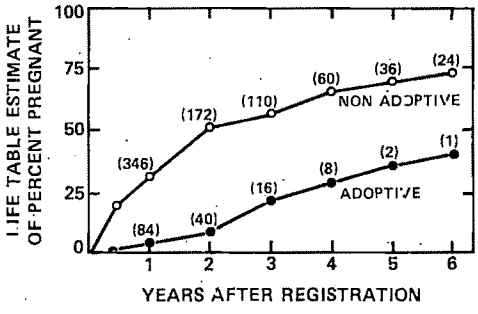

Fig. 3. Proportion of pregnancies achieved at various intervals after registration estimated by life-table methods. The number of couples still at risk of conception and under observation at each year after registration is indicated on the lines.

four groups (adoptive, not-adoptive, and the two strata of the covariates) for two covariates, duration of infertility and age of the wife at the time of registration. In none of the 14 comparisons in which the covariates were controlled did the difference in estimated risk ratio (adoptive/not-adoptive) reach the 0.05 level of significance. In one instance, that of a wife over 30 years old at registration, it approached this level.

Comment

A challenging aspect of the analysis of these data was the change in status of couples during the course of follow-up. Since many infertile couples evidence a fluctuating interest in adoption, we could not determine accurately which couple would and which would not become an adoptive couple until adoption had occurred. Adoptive couples must remain infertile at least long enough to adopt (Figs. 1 and 2). An analogous situation in which the treatment status changes during the course of follow-up is present in studies of heart transplant patients who are kept under observation until a suitable donor is found, at which time they re-

Table III. Effect of seven covariates on the risk ratio for conception (adoptive versus not-adoptive couples). An estimated risk ratio less than 1 and a negative Mantel-Haenszel statistic, M, indicate a lower risk of pregnancy for adoptive couples. The effect of the covariate on the risk of pregnancy was also estimated

ceive the transplant. We approached this problem in a way previously used for analysis of such data[4] by counting couples adopting during the course of the follow-up in the not-adoptive group until the day of the adoption and thereafter in the adoptive group.

Simple comparison of life tables for the adoptive and not-adoptive groups (Fig. 3) is definitely misleading if one fails to take into account possible reasons for these differences. The first was noted above—couples who adopt must remain infertile at least until the adoptive child is in their home; several other reasons will be discussed below.

Analysis of the entire observation period is necessary to estimate the relative risk of conception for couples in the two groups and to estimate the significance of the difference of this ratio from unity. Statistical methods used to estimate the relative risk and to test whether it differs significantly from 1 may be thought of as derived from the familiar chi-square test of independence used with a 2 by 2 contingency table. For this analogy one can imagine constructing a 2 by 2 contingency table for each discrete interval on the life-table graphs for comparison of the two groups. From the observed number in each of the four cells and from the marginal totals, one then determines the expected number for each cell. By passing an observation window across the entire life-table graph from the starting point and collecting the chi-square statistics as one goes, one can derive a summary chi-square statistic which would measure the significance of the difference between the two curves. The p value obtained could be considered the significance level at which one could just reject the null hypothesis that there is no difference in risk between the two groups.

A related statistic, M, proposed by Mantel and Haenszel to test the overall significance of such differences, is obtained by relating the sum of the differences in the individual cells to the sum of the variances.[9] For this study, we calculated the square root of this Mantel-Haenszel summary chi-square statistic (Table III).[4] This statistic has a normal rather than a chi-square distribution and the sign indicates the direction of the difference between the groups. A positive M indicates a greater chance of conception for adoptive couples; a negative M indicates a lesser chance, and an M of 0 indicates no difference. The M statistic calcu-

lated from our data was −0.208, a value which does no- differ significantly ($p = > 0.05$) from 0. In other words, the relative risk of pregnancy for those who hac adopted compared with those who had not did not differ significantly from 1.

Because of differences in sampling and censoring between the two groups the estimate of the relative risk itself was made by the regression method of Cox.[2] Discussion of the advantages and disadvantages of alternative methods of estimating risk ratios is beyond the scope of this paper. A recent review in the *British Journal of Cancer* discusses the general principles underlying these statistical methods in terms easily understood by medical investigators who are not familiar with statistical theory.[10]

We used the estimates of relative risks and their significance to identify and correct for two potential problems, one of which occurs late in the follow-up period and the other early in the follow-up period.

Late in the follow-up period, conception is less likely but adoption is still likely (Figs. 2 and 3). Those who adopt late are likely to be among the less fertile simply because couples then remaining under study are less likely to conceive. As shown in Fig. 3, the conception rate curve flattens out late in the follow-up period. The couples are now older, have been infertile longer, and have failed to prove themselves mildly infertile by conceiving early in follow-up. The methods of life-table analysis which were used in this study minimize this effect since comparisons of the risks of conception are made at equivalent times after registration.

Another problem in interpretation of the data is present early in the follow-up period, soon after the diagnostic survey. The least fertile are more likely to adopt then because couples judged to have a poor prognosis for conception are usually advised against delaying serious consideration of adoption.[7] Those who appear to have a good prognosis are not so advised and often do delay their decision at least for a time. By separate analysis of data for couples with or without various factors which might adversely affect fertility, we have attempted to identify and correct for variables which might affect the overall risk ratio. We determined the effect of the presence or absence of seven such covariates on the relative risk of conception for adoptive and not-adoptive couples. The absence of a significant difference in relative risk in any of these strata strengthens the conclusion reached about the total group.

Relative risks determined from a 2 by 2 contingency table are subject to the sources of error which we have discussed above. However, we could find only four publications (Table III) which provided enough data for even that type of analysis of overall conception rates comparing those who had adopted versus those who had never adopted.[1, 3, 11, 12] Additional comparison of these studies is impossible since each author used a different method of case selection and analysis. These previous studies have failed to end speculation about the therapeutic value of adoption for infertility. Other reports which merely related anecdotes or postulated explanations for the quasimystical effect of adoption will not be cited.

The practical difficulties of conducting an experiment, for example, one in which groups from a uniform population of infertile couples are randomly assigned to adopt or not to adopt, make it apparent that the question may never be finally settled. We considered the present study to be much more likely to provide an answer since the methods of statistical analysis controlled for changing treatment status during follow-up, for differences in the intervals between registration and adoption or conception, and for the presence or absence of several explanatory variables. This study does not provide support for the concept that adoption affects subsequent fertility.

Discussion

DR. RALPH C. BENSON, Portland, Oregon. The notion that adoption enhances fertility is shrouded in the mists of time. Certainly this belief has often been the sustaining hope in a barren marriage. Be this as it may, physicians have invoked this possibility as an escape after discouraging infertility study and treatment. In any event, like other old wives' tales, we should know whether this concept is true or false. Hence this investigation is a quest for truth or lack thereof.

Assuming that this hypothesis is correct, how could adoption improve fertility? There are a number of possibilities:

1. Divine intervention may result in pregnancy. Genesis 25:21 records the earliest case, "And Isaac prayed unto the Lord for his wife because she was barren; and the Lord granted his prayer and Rebeckah his wife conceived." How often such an invocation has been successful will never be known. Prayer is one approach to the cure of infertility but the Lord helps those who help themselves.

2. Therapeutic corrections may require a longer time than originally projected to become effective. Thus the couple may have become adoptive parents by the time pregnancy occurs.

Although one year usually is considered to be a reasonable period of time for pregnancy to ensue, a diminishing number of pregnancies will be recorded for months or even years later. If significant factors persist despite treatment, e.g., peritubal adhesions or oligospermia, more time may be necessary for pregnancy to occur.

Psychosomatic factors which may cause infertility are slow to resolve—with or without psychotherapy. For the man, these problems include functional impotence, premature ejaculation, or avoidance of coitus. Psychological improvement may lead to increased frequency of successful intercourse. For the woman, disturbances of ovulation and lack of disposition for intercourse during the known fertile period may be reversed. If one accepts the explanation that, in women, psychic conflicts lead to hormone disturbances via the hypophyseal-diencephalic system which cause infertility, the wife may ultimately "settle down" and reproduce. Unfortunately, evidence of this is fragmentary and uncontrolled. Nevertheless, if resolution does occur, it is more likely to be late than early because of the complexities involved.

Evidence that adoption does affect subsequent fertility is not persuasive. Scattered reports, most of which are anecdotal, suggest some benefit. However, clinical opinion is almost equally divided on this view. The limited number of studies assessed by Dr. Lamb and his co-workers have not proved their thesis, as he has indicated.

In this study, the authors have studied and treated a large number of patients and their follow-up is impressive. Moreover, they have gone to considerable lengths to be "fair" in their assumptions and comparisons. For example, they did not emphasize the fact that those patients who did adopt achieved fewer pregnancies than those who did not adopt (42.8% versus 32.0%). Their generous comment suggested that this is a "spurious" effect.

Dr. Lamb and his associates have estimated that had all not-adoptive couples been followed up for 5 years, 69% would have conceived. The corresponding points are 35% for adoption and 63% for all couples. Again adoption seems to have lost its reputed impact.

Certain guidelines must be made and often these are arbitrary, for example, "Until they had actually adopted, a couple was considered in the not-adoptive group." Adoption is a slow process. Hence this rule would seem to handicap the adoptive group to some extent. In addition, a small number of adoptions were arranged before registration and these women were included in the not-adoptive category. Despite these positive decisions, it is likely that such restrictions lead to underestimates of adoption rates but do not affect the calculation of conception rates.

Be this as it may, I am bothered by the implication that adoption could be arranged promptly so that the woman would quickly pass to a new group. For example, it is stated, "Late in the follow-up period, conception is less likely and adoption is more likely." Also (later), "The least fertile are more likely to adopt early than late because couples judged to have a poor prognosis for conception are usually advised against delaying serious consideration of adoption." This suggests that adoption was a prompt achievement. How often and how soon was adoption accomplished? Years may pass in Oregon before adoption is possible because of the considerable demand and relatively few children available for adoption.

On a positive note, I am most impressed by the elegant statistical methods of evaluation employed. The control of seven covariates which could affect the conception rate should be more than ample and the conclusions are most reasonable and convincing.

The authors did not answer their original question, "Does adoption affect subsequent fertility?" with one word. Their scholarly conclusion is that their study does not provide support for this concept. Nonetheless, for clinical purposes I believe that we can now state categorically that fertility is *not* enhanced by adoption.

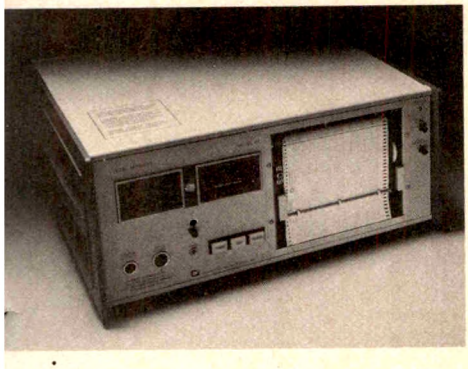
DR. WILLIAM O. THOMAS, JR., Portland, Oregon. The point I will make here is possibly more philosophical than scientific. I think that all of us have had the impression, over the years, that adoption does make a difference in these couples. However, as mentioned by Dr. Benson, it seems to me that the only possible situation where adoption could have any effect would be in the couple in whom the psychosomatic

LIBRARY

factors predominate. By that I mean that obviously, if there is extensive tubal damage or other organic pathology in the woman, or any severe pathology as far as the man is concerned, adoption will not have any effect either way. Therefore, I would be most interested in patients in whom all pathology had been completely ruled out and only the psychosomatic factors were to be dealt with, and then the effect of adoption on that group could be determined. With my simple mathematics, I still come up with the fact that of those who did not adopt, 42% conceived, and of those who did adopt, only 32% conceived. But I will admit, Dr. Lamb, that this was a masterful presentation on how to explain that difference away.

DR. EUGENE C. SANDBERG, Stanford, California. I would like to mention one variable that appears not to have been considered, the availability of an infant for adoption. During the years in which these couples were collected and studied, there was a sharp and steady decline in the number of adoptable infants. Consequently, a free selection by the couples of their category, adoptive or not-adoptive, was not possible. It may be that some couples were forced into the not-adoptive group even though their adoptive attitude and psychological makeup (whatever effect this might have on fertility) more closely paralleled those of couples in the adoptive group.

DR. LAMB (Closing). Dr. Benson expressed concern about our analytic model in which subjects were changed from the control (not-adoptive) to the treatment (adoptive) group during the course of the follow-up. A similar model had been developed for study of patients being considered for a heart transplant. They waited an unpredictable period until a donor became available. Those who have a transplant then changed treatment status. Those who died before a donor was found served as the control group.



We have difficulty identifying a group with unexplained infertility in whom no organic disorder is present. After thorough investigation of both partners, including routine pelvic endoscopy, we usually find one or more factors which reduce fertility to one degree or another. When we restrict analysis to a group in which none had any one of several combinations of the factors listed in column 2 of Table III, the number of cases remaining is too small to allow meaningful comparisons.

During the interval 1963 to 1976 when intake for this study occurred, the number of infants relinquished for adoption in California fell from about 12,000 to about 3,000. Had we asked the question, "Does the advice to adopt or the desire to adopt affect subsequent fertility?" this fourfold reduction in babies adopted would certainly have a bearing. This was one reason why we chose to ask the question, "Does adoption (bringing the child into the home) affect subsequent fertility?"

A problem delivery that came out just fine.

For 5 years our 111 Fetal Monitor has been helping physicians and patients through countless problem pregnancies and deliveries, its performance clinically proven.

The 111 is an intrapartum monitor, a reliable workhorse no hospital obstetrics department should be without. It monitors FHR three ways: through ultrasound, directly using spiral electrodes, or by an optional phonotransducer. A tocotransducer or intrauterine catheter and strain gauge measure uterine activity.

This is the fetal monitor to which all others are compared, the standard of the industry.

The Corometrics 111 Fetal Monitor works with you for safer deliveries. For more information contact: Corometrics Medical Systems Inc., 61 Barnes Park Road North Wallingford, Connecticut U.S.A. 06492, (203) 265-5631.

21 peach tablets of norethindrone 0.4 mg and ethinyl estradiol 0.035 mg.
Each green tablet in the 28-day regimen contains inert ingredients.

More than dosage may be reduced...

Mead Johnson PHARMACEUTICAL DIVISION

For Brief Summary, please see last page of this advertisement.

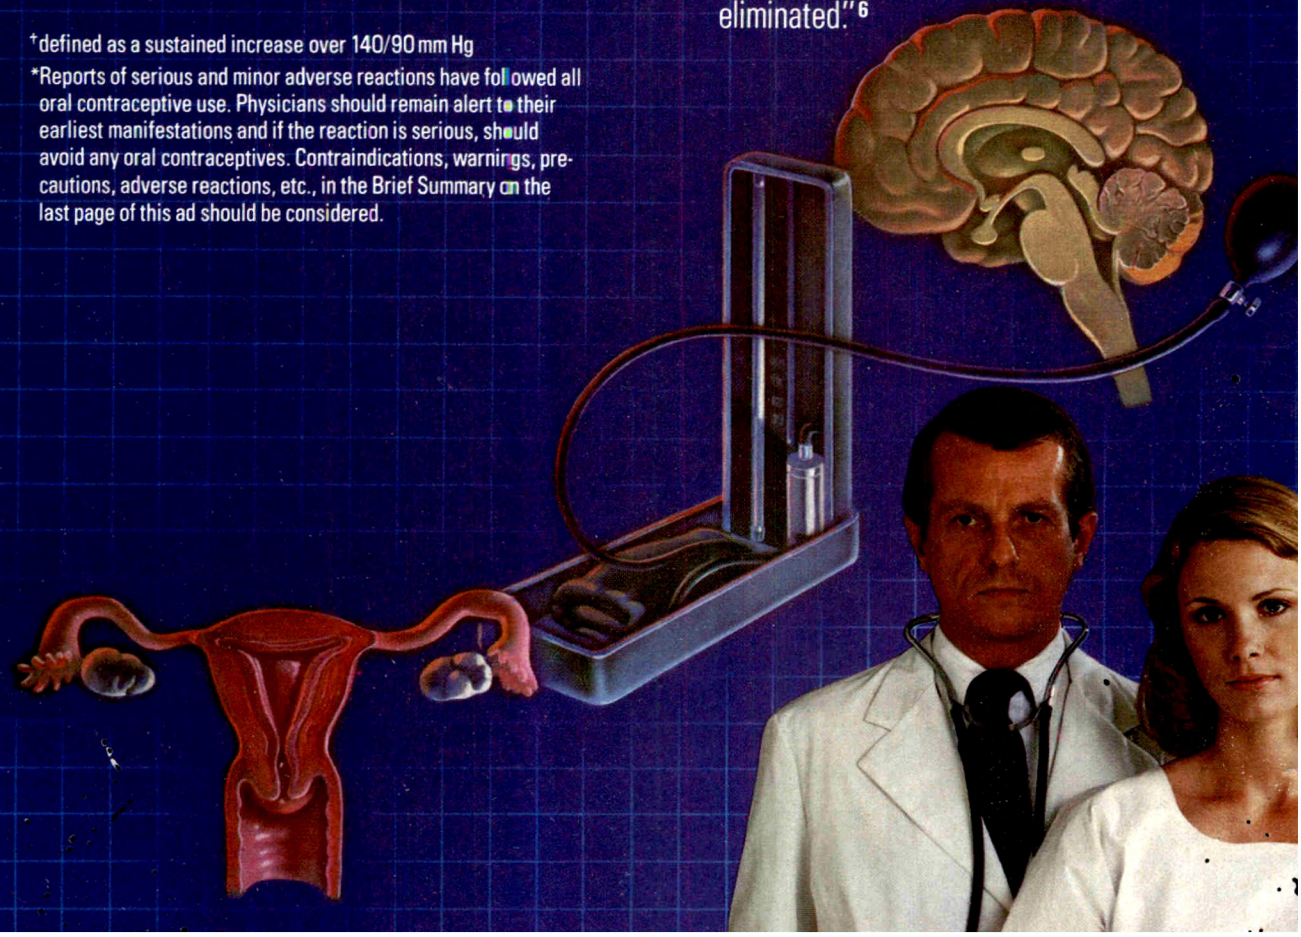
Research to date suggests that

reducing dosage may reduce risk*[1-3]

OVCON®-35 provides effectiveness

21 peach tablets of norethindrone 0.4 mg and ethinyl estradiol 0.035 mg.
Each green tablet in the 28-day regimen contains inert ingredients.

1 No hypertension†



- No hypertension developed in 564 normotensive women during 44 months of one study[5]
- No hypertension was observed in 1,925 of 1,970 women during original clinical experience[4]
- Blood pressure did not increase during 8–18 months of OVCON-35 therapy in four women who were initially hypertensive[5]
- Eighty-four women with histories of toxemia of pregnancy showed no significant differences in blood pressure from 480 women with normal pregnancy histories[5]
- Prevalence of hypertension increases with longer oral contraceptive use and age

†defined as a sustained increase over 140/90 mm Hg

*Reports of serious and minor adverse reactions have followed all oral contraceptive use. Physicians should remain alert to their earliest manifestations and if the reaction is serious, should avoid any oral contraceptives. Contraindications, warnings, precautions, adverse reactions, etc., in the Brief Summary on the last page of this ad should be considered.

2 No significant adverse changes in weight, plasma insulin levels, blood glucose values, or fasting triglyceride and cholesterol levels in a preliminary prospective study[6,7]

"Although these data are very preliminary in that they represent only a small number of women (seven) treated for only a short period of time (6 months), they are exciting, for they suggest that perhaps oral contraceptive development has reached a stage where some of the adverse effects have been greatly reduced or eliminated."[6]

and reduced dosage[4-6]

3 OVCON-35 appears to permit prompt return of endometrial function[5]

- In 125 randomly selected women, endometrial biopsies performed during the luteal phase of the first postcontraceptive cycle after up to 36 months of therapy, showed no inactive endometria
- No amenorrhea was seen, although mean cycle length for the first postcontraceptive cycle was slightly prolonged
- It cannot be assumed that amenorrhea will not occur in any patient population using oral contraceptives

4 Low incidence of breakthrough bleeding and spotting

- In one study with OVCON-35, the incidence of breakthrough bleeding was 9.1% and that of spotting was 4.7% during the first cycle of therapy; the incidence decreased to 3.2% and 1.9%, respectively, by cycle 39[5]
- Overall clinical experience with OVCON-35 (20, 230 cycles) shows an average combined incidence of breakthrough bleeding and spotting of 16.2%[4]

5 Provides "method effectiveness that does not differ from published method effectiveness rates of higher-dose products"[5]

- Pregnancy rate of 0.21 (Pearl Index, method effectiveness) in one study of 700 patients completing 17,294 cycles[5]
- Method effectiveness of 0.41 (Pearl Index) and a use-effectiveness of 1.36 (Pearl Index) in 20,230 cycles in original clinical trials[4]

OVCON-35®

Mead Johnson

Indications and Usage: Ovcon is indicated for the prevention of pregnancy. Some combination products containing 35 mcg. or less of ethinyl estradiol report slightly higher pregnancy rates than are reported for the higher dose combination products.

Contraindications: Oral contraceptives should not be used in women with any of the following conditions: 1) Thrombophlebitis or thromboembolic disorders. 2) A past history of deep vein thrombophlebitis or thromboembolic disorders. 3) Cerebral vascular or coronary artery disease. 4) Known or suspected carcinoma of the breast. 5) Known or suspected estrogen dependent neoplasia. 6) Undiagnosed abnormal genital bleeding. 7) Known or suspected pregnancy.

Warnings:

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. Women who use oral contraceptives should be strongly advised not to smoke. Use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1) *Thromboembolic Disorders and Other Vascular Problems.* An increased risk of thromboembolic and thrombotic disease associated with use of oral contraceptives is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. In a study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.6 times greater than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater. An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported. Studies conducted in the United Kingdom found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction compared to nonusers who do not smoke. Oral contraceptive users who smoke have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. The amount of smoking is a very important factor. British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; preparations containing 100 mcg. or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg. of estrogen. The relative risk of thromboembolic disease associated with progestin-only oral contraceptives has not been determined. Cases of thromboembolic disease have been reported in women using progestin-only products, and they should not be presumed to be risk-free. The overall excess mortality rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-35: 5/100,000; ages 35-44: 33/100,000; ages 45-49: 140/100,000); the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. The highest risk was found in heavy cigarette smokers (15 or more cigarettes per day) who used oral contraceptives and were aged 40 or older. Women who smoke should be advised not to use oral contraceptives. The use of oral contraceptives in women over age 40 with other risk factors is not recommended. The mortality associated with all of the methods of birth control is low compared to the risk of childbirth, with the exception of oral contraceptive users who smoke and are over age 40. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and for myocardial infarction is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. If feasible, oral contraceptives should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2) *Ocular Lesions.* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue the medication if there is unexplained sudden or gradual partial or complete loss of vision; sudden onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3) *Carcinoma.* Long term administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. In humans, one study investigated the first 21 cases of endometrial adenocarcinoma in women on oral contraceptives reported to a registry. Of those women without predisposing risk factors for this disease, nearly all occurred in women who had used a sequential oral contraceptive. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestin-only oral contraceptives. No increase in breast cancer in women taking oral contraceptives has been reported although one study reported an increased risk of breast cancer in subgroups of women treated using oral contraceptives with documented benign breast disease. There is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives. 4) *Hepatic Adenoma.* Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study reported a higher risk associated with oral contraceptive formulations with high hormonal potency. Although benign and rare, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short term as well as long term users of oral contraceptives. Two studies relate the risk with duration of contraceptive use: the risk being much greater after 4 or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5) *Use in Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring.* Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. A high percentage of such exposed women (30% to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Similar data are not available with the use of other estrogens but it cannot be presumed that they would not induce similar changes. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications and there is no evidence from well-controlled studies that progestins are effective for these uses. Increases in chromosomal aberrations have been reported in women who become pregnant soon after ceasing oral contraceptive therapy. Embryos with these anomalies are virtually always spontaneously aborted. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed the patient should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation should be discussed in light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months. Administration of progestin-only or progestin-estrogen combinations to induce withdrawal bleeding should not be used as a test for pregnancy. 6) *Gall Bladder Disease.* Studies have reported an increased risk of surgically confirmed gallbladder disease appearing after one year of oral contraceptive use and doubling of the risk after 4 or 5 years of use. 7) *Carbohydrate and Lipid Metabolic Effects.* A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. Increased serum levels of triglycerides and total phospholipids have been observed in oral contraceptive users. The clinical significance of this observation is unknown at this time. 8) *Elevated Blood Pressure.* An increase in blood pressure has been reported in women receiving oral contraceptives. The prevalence of hypertension in oral contraceptive users may be no higher than nonusers in the first year of oral contraceptive use but increases with longer exposure and in the fifth year of use is two and one-half to three times the reported prevalence in the first year. Women who previously had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. 9) *Headaches.* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of oral contraceptives and investigation of the cause. 10) *Bleeding Irregularities.* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. 11) *Ectopic Pregnancy.* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in oral contraceptive failures, the ratio of ectopic to intrauterine pregnancies is higher than in women not using oral contraceptives since the drugs are more effective in preventing intrauterine rather than ectopic pregnancy. The higher ectopic-intrauterine ratio has been reported with both combination products and progestin-only oral contraceptives. 12) *Breast Feeding.* A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

Precautions: 1) A complete medical and family history should be taken prior to the initiation of oral contraceptives. Examination should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than 1 year without another physical examination being performed. 2) Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3) Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 4) Because oral contraceptives may cause some degree of fluid retention, conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, cardiac or renal insufficiency or asthma require careful observation. 5) Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6) Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7) Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8) Serum folate levels may be depressed by oral contraceptive therapy. This may complicate subsequent pregnancy with regard to folate deficiency. 9) The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10) Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient: Detailed Patient Labeling has been prepared for use by the patient and has been made available for distribution by the pharmacist.

Drug Interactions: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium and ampicillin.

Adverse Reactions: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **Warnings**): Thrombophlebitis; pulmonary embolism; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gall bladder disease; congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis; benign hepatomas; neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle (Other reactions, as a general rule, are seen much less frequently or only occasionally.); gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes (tenderness, enlargement, and secretion); change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome; intolerance to contact lenses; change in corneal curvature (steepening); cataracts; changes in libido; chorea; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis; porphyria; impaired renal function.

Acute Overdosage: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Bilateral internal iliac artery ligation in cervical pregnancy: Conservation of reproductive function

RONALD M. NELSON, M.D.
Loma Linda, California

Like other forms of ectopic gestation, cervical pregnancy is a serious complication with potentially life-threatening consequences. Excessive bleeding almost invariably follows an attempt to evacuate this rare ectopic pregnancy. In most reported cases, hysterectomy has been required to control the severe hemorrhage. This paper reports for the first time the successful conservative management of cervical pregnancy in two patients by bilateral internal iliac artery ligation alone. Early recognition of the cervical pregnancy and prompt internal iliac artery ligation are stressed. (AM. J. OBSTET. GYNECOL. 134:145, 1979.)

CERVICAL PREGNANCY is a rare form of ectopic gestation in which implantation occurs in the cervical mucosa below the level of the internal os of the uterus. Like other forms of ectopic gestation, cervical pregnancy is a serious complication with potentially life-threatening consequences.

In 1953, Baptisti[1] said that most obstetricians would never see a cervical pregnancy and that those who did encounter the complication would wish they had not. This warning was occasioned by the severe bleeding that almost invariably attends either the spontaneous abortion or surgical evacuation of this pregnancy. In most reported cases, multiple transfusions and total abdominal hysterectomy have been required to control the hemorrhage. The resulting loss of childbearing function in a young patient with low parity is a central concern in the surgical management of cervical pregnancy.

This paper reports for the first time the successful conservative management of cervical pregnancy in two patients by bilateral internal iliac artery ligation alone. These cases demonstrate that in some patients the ligation of the internal iliac arteries may be an effective alternative to hysterectomy in the treatment of cervical pregnancy.

From the Department of Obstetrics and Gynecology, Loma Linda University Medical Center.

Presented by invitation at the Forty-fifth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Gleneden Beach, Oregon, September 26-30, 1978.

Case reports

Case 1. C. B., a 17-year-old single woman, gravida 1, para 0, was admitted to the Gynecology Service at Loma Linda University Medical Center on January 3, 1970, after 3 weeks of cramping, lower abdominal pain, abnormal vaginal bleeding, and the presence of a pelvic mass. Her last menstrual period was November 28, 1969. The abdominal pain began with the onset of abnormal bleeding and progressively increased in intensity. Two weeks prior to this admission, an intravenous pyelogram and barium enema suggested the presence of a pelvic mass. A gynecologic consultation at that time confirmed a pelvic mass the size of a 12 week intrauterine pregnancy. However, a pregnancy test was negative. Sexual intercourse had occurred three months prior to hospitalization.

On admission, the patient's blood pressure was 120/76 mm Hg, pulse 100 bpm, and temperature 97° F. The findings of the general physical examination were normal. The abdominal examination revealed a readily palpable, firm, tender, suprapubic mass. There was no rebound tenderness. The cervix was closed, with some dark blood coming from the external os. A 10 to 12 cm soft, cystic, globular mass was found to be filling the pelvis. The cervix and uterus could not be readily distinguished from the mass, which projected into the posterior fornix of the vagina and appeared to displace the cervix anteriorly. The adnexa were not palpable. A urinary pregnancy test was negative and the urinalysis normal. The hemoglobin was 12.8 gms/100 ml and the white blood cell count was 14,200/cu mm with a slight shift to the left.

An exploratory laparotomy was performed on January 5, 1970, and showed the uterine corpus to be of normal size but elevated out of the pelvis by a 10 cm soft, cystic enlargement of the cervix. The tubes and

ovaries were normal. A diagnosis of cervical pregnancy was first considered at this time. The patient was placed in a low lithotomy position and redraped. Cautious exploration of the cervix with a uterine sound and with direct observation through the laparotomy incision revealed a marked dilatation and thinning of the cervical canal. The internal os was intact and the endometrial cavity was normal. Brisk, active bleeding was encountered during the exploration of the cervix. Because of the patient's age and parity, a bilateral internal iliac artery ligation was performed prior to any further attempt to evacuate the cervical pregnancy. The ligation was accomplished without difficulty. The cervix was then carefully curetted and a large amount of necrotic placental tissue and old clot was removed from the endocervical wall. Minimal bleeding was encountered during the evacuation, the total estimated blood loss during the procedure being 250 ml. No uterine packing was required and the patient's postoperative course was uneventful. The pathologic examination of the surgical curettings revealed portions of partially necrotic decidual tissue and chorionic villi.

The patient again became pregnant in February, 1973. The pregnancy terminated at 8 weeks with an incomplete, infected abortion. In September, 1974, total abdominal hysterectomy and bilateral salpingo-oophorectomy were required for chronic pelvic infection and recurrent bilateral tuboovarian abscesses.

Case 2. M. G., a 33-year-old married woman, gravida 3, para 2, abortions 0, was admitted to Loma Linda University Medical Center on March 16, 1971, with profuse vaginal bleeding at 11 weeks' gestation. Her last normal menstrual period was January 1, 1971. She had been seen in the outpatient clinic two weeks prior to admission, complaining of dark brown vaginal discharge. A pregnancy test was positive. A diagnosis of threatened abortion was made. On the day of admission, the patient was re-examined for heavier vaginal bleeding and cramping abdominal pain for the previous 9 days. The external os of the cervix was dilated 2 cm with a moderate amount of dark blood coming from the os. The uterus was enlarged, consistent with an 11 week pregnancy. A forceps was introduced through the dilated external os and an enlarged cystic cavity of the cervix was noted. Excessive vaginal bleeding followed immediately with a sudden loss of approximately 300 ml of blood. Intravenous fluids were started at once and the patient was taken directly from the outpatient clinic to the operating room for emergency surgery for a suspected cervical pregnancy.

Her past medical history revealed two previous cesarean sections, but there had been no previous gynecologic surgery. She had been treated for sarcoidosis in 1970.

On admission, the patient's blood pressure was 130/100 mm Hg, pulse 100 bpw, temperature 98.6° F. The preoperative hemoglobin was 11.6 gm/100 ml. The patient was given a general anesthetic agent, placed in a low lithotomy position, and prepared and draped for a combined vaginal and abdominal surgical approach. The cervical cavity and uterus sounded to 13 cm. The

internal os appeared intact and the endometrial cavity was normal. A 6 to 8 cm sacculation of the cervix was noted. An attempt to evacuate the pregnancy from the cervix resulted in further active, uncontrollable bleeding. At laparotomy, the cervix was approximately 8 cm in diameter, with a very thin cervical wall. On top of the cervix was a normal-sized uterine corpus. Because the patient desired to maintain her fertility, a bilateral internal iliac artery ligation was performed. The cervix was then thoroughly curetted. Moderate bleeding continued from the cervix but was well controlled with intracervical packing. The estimated total blood loss was 1,200 ml. The patient received 2 U of whole blood postoperatively. The pathology report revealed necrotic decidual tissue with chorionic villi consistent with cervical pregnancy.

Follow-up examinations revealed the resumption of regular, normal menstrual periods. A basal body temperature recording and endometrial biopsy confirmed ovulation. A hysterogram revealed a normal endocervical cavity and an intact internal os. The patient started oral contraceptive pills within 1 year following surgery and has continued to use contraception to the present time.

Comment

Cervical pregnancy is one of the rarest forms of ectopic gestation. Breen[2] reviewed 654 ectopic pregnancies encountered in 56,700 deliveries over a 20 year period. Only one cervical pregnancy (0.15%) was reported in this large series. Because cervical pregnancy is extremely rare, its reported incidence is highly variable. In 1966, Dees[3] recorded an incidence of one cervical pregnancy in 18,000 pregnancies. Sheldon and colleagues[4] reported a similar frequency of 1:16,000 over a 15 year period. On the other hand, Shinagawa and Nagayama[5] found a remarkably high incidence of one in 1,000 pregnancies in Japan.

Cervical pregnancies are infrequently reported in the literature. In 1961, Thomsen and Johansen[6] found only 80 recorded cases. In 1968, Heller[7] stated that approximately 120 cases had been described up to that time. Since 1968, 38 documented cases of cervical pregnancies have been reported in the English literature. These cases and their method of therapy are summarized in Table I.[7–19] Nineteen of the 38 case reports (50%) are from a single report from Japan. If these are excluded, there remain only 19 cases of cervical pregnancy in the English literature over the past 10 years. A summary of some pertinent clinical findings in these 38 cases of cervical pregnancy is presented in Table II.

The etiology of cervical pregnancy is unknown. Two factors appear to contribute to an ectopic cervical implantation: a previous surgical manipulation of the cervix (curettage) and a previous pregnancy. Shinagawa and Nagayama[5] attributed the apparent higher incidence of cervical pregnancy in Japan to the high frequency of therapeutic abortions in that country. They reported that 68% of 19 patients with cervical pregnancy had undergone an antecedent therapeutic abortion. In a control group of 200 women, a previous therapeutic abortion was found in only 32% (Table III).

In the remaining 19 cases of cervical pregnancies reported in the last 10 years, a history of a previous curettage was found in 63%. A control group of 53 patients admitted to Loma Linda University Medical Center for incomplete abortion was selected at random for comparison (Table III). All primigravid women were excluded. Eighteen (34%) of these patients had an antecedent curettage. This difference between the cervical pregnancy and control groups is statistically significant ($P < 0.05$).

A second possible etiologic factor is multigravidity. The large majority of patients have had several previous pregnancies. The average gravidity of the previous 38 patients with cervical pregnancy was 4.7. Only six cases of cervical pregnancy in patients in their first pregnancy have been reported.[17] One of the cases in

this report is the seventh recorded instance of a cervical pregnancy in a primigravid patient.

The diagnosis of cervical pregnancy is infrequently made prior to surgery. The preoperative diagnoses of all cervical pregnancies reported in the last 10 years are listed in Table IV. The most frequent diagnosis was imminent or incomplete abortion. In only seven patients (18%) was a diagnosis of cervical pregnancy suspected prior to operative intervention. The wide variety of preoperative diagnoses indicates the frequently confusing clinical picture presented by these patients.

Early diagnosis of cervical pregnancy depends upon the obstetrician's constant awareness of its possibility and a very careful evaluation of the pelvic findings. Recently the diagnosis of cervical pregnancy by ultrasound has been reported.[19] The more frequent utilization of ultrasonography in the evaluation of vaginal bleeding in early pregnancy may increase the possibility of preoperative recognition of this complication.

In 1911, Rubin[20] set forth specific pathologic criteria as necessary to establish the diagnosis of cervical pregnancy: (1) the cervical glands must be opposite the placental attachment; (2) placental attachment to the cervix must be intimate; (3) the whole or a portion of the placenta must be situated below the entrance of the uterine vessels or below the peritoneal reflection of the anterior and posterior surfaces of the uterus; (4) fetal elements must not be present within the corpus uteri. Not all reported cases of cervical pregnancy have met these requirements because Rubin's criteria require pathologic examination of the excised uterus obtained either from surgery or from autopsy. Therefore, in 1959, Paalman and McElin[21] suggested several clinical objective signs to establish a diagnosis of cervical pregnancy: (1) a softened and disproportionately enlarged cervix equal to or larger than the corporal portion of the uterus, (2) products of conception entirely confined within and firmly attached to the endocervix, (3) a snug internal os, and (4) a partially open external os. The two cases presented in this report meet these criteria.

Approximately 90% of the reported cases of cervical pregnancy during the past 10 years have required total abdominal hysterectomy to control excessive bleeding (Table I). A conservative management of cervical pregnancy by curettage, cervical packing, ligation of the cervical arteries, and suturing of the cervix has been successful in only a small number of patients. The majority of the conservatively managed cases have been in pregnancies of less than 8 weeks. When the pregnancy has progressed beyond 8 weeks, major bleeding is usually encountered and hysterectomy is necessary.

In 1965, Dodeck[22] suggested the consideration of bilateral ligation of the internal iliac arteries along with a transabdominal cervicotomy as a conservative approach to the advanced cervical pregnancy. However, he did not have any experience with this approach. Internal iliac artery ligation has been reported in conjunction with abdominal hysterectomy in several cases of cervical pregnancy in which severe bleeding and unusual complications existed.[4, 17] The only previous report of an attempt to perform internal iliac artery ligation for hemostasis was by Shinagawa and Nagayama.[5] In reporting their 19 cases of cervical pregnancy, they stated that they were unable to obtain satisfactory hemostasis by ligation of the internal iliac arteries. However, they did not list the number of cases in which internal iliac artery ligation was attempted or describe the circumstances surrounding the failures.

Internal iliac artery ligation is rarely performed by obstetricians and gynecologists. In 1973, Sack[23] reported that 94% of obstetrics and gynecology specialists he surveyed in Southern California had not performed the procedure in a 10 year period. He found that most ligations were performed in large teaching centers. However, he stressed that all pelvic surgeons should maintain their proficiency in this procedure by occasionally exposing and identifying the internal iliac arteries during the course of other pelvic surgery. Demonstration of the technique, if not the actual ligation of the arteries, should be an integral part of every residency training program.

Pregnancy following bilateral internal iliac artery ligation is well documented.[24] The subsequent pregnancies have been normal with normal deliveries, and there has been no increased incidence of obstetric complications. The prognosis for future pregnancies following the conservative management of a cervical gestation is unknown because of insufficient experience to determine the likelihood of complications in subsequent pregnancies. However, normal pregnancies and vaginal deliveries after a previous cervical

pregnancy have been reported.[1, 4] Cervical incompetence would be unexpected unless the internal os was compromised during surgery. The risk of a subsequent cervical pregnancy is unknown.

This report documents for the first time the successful management of a cervical pregnancy by bilateral internal iliac artery ligation. Conservation of reproductive function was achieved. In addition, the amount of blood loss in these two patients was considerably less than has been reported in the literature in similar circumstances. Furthermore, by this approach, the evacuation of the products of conception can be safely and thoroughly accomplished through the vagina.

Discussion

Dr. Frank LeCocq, Jr., Yakima, Washington. In this age of advanced medical knowledge and technology, a "first time" report is rare, yet Dr. Nelson has described and for the first time successfully utilized a surgical technique in the treatment of a catastrophic obstetric complication. Being a longtime champion of the use of internal iliac artery ligation, I am privileged to discuss and confirm this accomplishment. As has been stated, various authors have suggested but did not utilize the technique. Finally internal iliac artery ligation was performed in cervical pregnancy, but in conjunction with total abdominal hysterectomy. In reviewing all of the available literature, I can confirm that Dr. Nelson may take credit for the first successful use of internal iliac artery ligation in the preservation of child-bearing function in cervical pregnancy.

This rare nidation and development of an ectopic pregnancy in the cervix presents overwhelming problems in diagnosis and management. Any discussion of this interesting lesion could include Studdiford's[1] classic publication on this subject in 1945. He discussed 28 cases, including Tarnier's fatal case of cervical pregnancy in 1887 resulting in the delivery of a viable term infant. Also described was Connor's unique case of cervical pregnancy occurring in a cervical stump following a previous supracervical hysterectomy. Aside from these medical oddities, Dr. Nelson has adequately brought us to the present, referable to the clinical aspects of this most infrequent but important lesion.

The pathophysiology of the hemorrhage is based upon nidation of the ovum in a most vascular area of the uterus, which unfortunately consists of only 15% musculature with contractile potential. The rarity of the condition in itsself leads the unsuspecting clinician into the "valley of the shadow," not anticipating the horrendous bleeding that will follow attempts at its removal. Dr. Nelson noted that only 18% of all reported cases were considered as cervical pregnancy prior to surgery. Though extremely rare, this condition must be considered by the clinician to avoid catastrophic and even fatal hemorrhage. In the past, only 10% of cervical pregnancies have been treated with less than hysterectomy, and these invariably were within the early

weeks of gestation. Used were various techniques of curettage, packing, and suture.

Maintenance of child-bearing function following internal iliac artery ligation has been a fascinating chapter in the evolution of this surgical procedure. The unique, efficient collateral blood supply of the pelvis, so well described by Burchell,[2] must be reconsidered. Mengert and Burchell[3] have accumulated five cases in which pregnancy has occurred following internal iliac artery ligation; moreover, in three cases bilateral ovarian artery ligation was performed as well. In a recent report from Mexico,[4] 90 cases of internal iliac artery ligation were described, of which the uteri were retained in 22 cases. Of these, seven patients subsequently became pregnant. In a recent personal communication from Burchell,[5] the use of absorbable suture material in the ligation is suggested. This will enhance recanalization of the ligated vessels and thus aid in preserving fertility.

In discussing the etiology of cervical pregnancy, previous surgical trauma, older age, multiparity, abortion, leiomyomas, uterine atrophy, malformations, and even oral contraceptives have been considered by various authors as contributing factors. Certainly the Japanese observation that over 60% of their cases of cervical pregnancy were preceded by therapeutic abortion is indisputable. I would question Dr. Nelson's use of 53 random clinic patients as controls to support this conclusion.

In that Dr. Nelson's publication gives us still another indication for internal iliac artery ligation, I would again like to advocate the teaching of the technique to all operating gynecologists. Although rarely necessary, its use can be lifesaving. I recall, with some amusement, a "Letter to the Editors" of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY following our last discussion of this topic in 1973. Dr. Buschbaum,[6] of Chicago, commenting on our meeting, indignantly wrote, "Operating in the pelvis without the ability to do a hypogastric artery ligation is similar to teaching an electrician intricate wiring circuits without first teaching him to turn off the current."

I wish to thank Dr. Nelson for his prompt submission of this document and congratulate him on this exciting contribution to the medical literature. In that the duration of pregnancy is vital in the treatment and prognosis, I will conclude with a question regarding his Case No. 1: Does he speculate the duration of this pregnancy was 3 weeks as indicated by the menstrual history or possibly 12 weeks as indicated by the clinical findings or the social history?

DR. RICHARD N. BOLTON, Portland, Oregon. I would like to ask Dr. Nelson if he has had any experience, or knows of anyone else who has had any experience, using a high cervical cerclage type of procedure for this form of bleeding—something like you would use for an insufficient cervix.

DR. NELSON (Closing). There is one report in the European literature of an approach similar to a cerclage type of procedure. They actually clamped and ligated the cervical branch of the uterine artery, as done in performing a vaginal hysterectomy, and were successful in controlling the bleeding.

In answer to the question about the duration of pregnancy in Case No. 1, I would have assumed by the size of the cervical enlargement, despite the recent menstrual period within three weeks, that the pregnancy was further advanced than stated. According to our biostatistician, there were sufficient numbers in the study for the control group to pass a chi-square test for validity of the analysis.

In reviewing the past published reports, a rather common theme seemed to develop—late first-trimester or early midtrimester bleeding, a diagnosis of incomplete abortion, and attempted evacuation of the pregnancy with resulting uncontrollable hemorrhage and hysterectomy. One does not undertake bilateral internal iliac artery ligation without considerable concern. However, when one considers the alternatives for these patients, it seems an appropriate choice in selected patients.

Vasa previa

DAVID PENT, M.D.

Tucson, Arizona

An active obstetric service can expect to have one perinatal death each year due to vasa previa. Unfortunately, little has been done to improve the diagnosis and treatment of this condition, which presents no risk to the mother but is often fatal to the fetus. The various clinical pictures which can be associated with vasa previa are presented, along with a discussion of the techniques readily available for making the diagnosis: palpation and visualization, amnioscopy, fetal heart monitoring, and various tests for the presence of fetal hemoglobin. (AM. J. OBSTET. GYNECOL. 134:151, 1979.)

THE PAST DECADES have seen the development of a wide array of chemical, physical, and electronic techniques designed to detect even subtle changes in the fetal environment and threats to fetal well-being. Yet vasa previa, with one of the highest fetal mortality rates of any obstetric condition, continues to receive scant attention. Indeed most obstetricians look upon its diagnosis and management with utter despair, lack any familiarity with the various clinical features of the condition, and consistently fail to utilize the techniques which are available for establishing the diagnosis.

Although vasa previa is certainly not common, Driscoll[1] reported one death per year from vasa previa at the Boston Lying-In Hospital. The incidence of vasa previa is in the range of one for each two thousand to three thousand deliveries,[2, 3] and it is quite possible that with increased knowledge of the problem the true incidence is even higher. Thus a moderately active obstetric service can expect one case each year.

It is the purpose of this paper to present a case report followed by a discussion of the diagnosis and treatment of vasa previa, in the hope that with awareness of this problem fetal survival will increase.

Case report

The patient was a 26-year-old woman, gravida 3, para 2, with an uneventful prenatal course, admitted to the hospital at 41 weeks' gestation. The membranes had ruptured spontaneously 1 hour earlier. At the time of admission, a sheet of the membranes, approximately 15 cm in length, was extending out from the vaginal introitus, lying up against the patient's right thigh. This was lifted up—and possibly some slight traction exerted—by the aide shaving the vulvar area. This handling of the sheet of membranes was followed by a gush of bright red blood.

Fetal movements were no longer felt by the patient and fetal heart tones could no longer be heard. During labor, which was augmented with oxytocin, the severed end of the umbilical cord prolapsed through the vagina, making the diagnosis obvious. After 3½ hours of labor the patient was delivered of a 7 pound, 14½ ounce stillborn male infant. The placenta was delivered and demonstrated a velamentous insertion of the umbilical vessels with rupture.

Clinical features

Most obstetricians, when they think of vasa previa, picture the same sequence of events that occurred in this case: spontaneous rupture of the membranes, laceration of the umbilical vessels, fetal hemorrhage, and subsequent fetal death. However, this is by no means the universal picture. Previous authors[4–6] have clearly demonstrated that many, sometimes the majority, of cases of vasa previa are of such a nature as to permit the diagnosis to be made and treatment to be instituted. A high index of suspicion is important in making the diagnosis and this requires a familiarity with the various clinical features associated with vasa previa:

1. Bleeding need not be present. Vasa previa is defined as an anomaly of the insertion of the umbilical cord into the placenta in which the umbilical vessels traverse the lower uterine segment and present in advance of the fetal presenting part. Thus, even if there is no rupture of the blood vessels, these may be compressed against the bony pelvis by the fetal head, resulting in hypoxia and possible fetal death. Whereas vasa previa with bleeding is associated with fetal death in 75% to 100% of cases, fetal death secondary to cord

compression has a reported incidence of 50% to 60%.[7, 8]

2. The vessels do not have to traverse the os. This anatomy does not fit precisely into the definition of vasa previa, but the clinical picture, diagnosis, and treatment of the patient are the same as in vasa previa. Torrey[9] has classified this occurrence as a separate group, which he called "abruptio of the umbilical vessels." The mechanism involved is a tear in the amniotic sac which extends into the velamentous vessels.

3. The membranes need not be ruptured. A velamentous insertion of the cord is a prerequisite for vasa previa. As such, the vessels are no longer protected by Wharton's jelly and are particularly vulnerable to rupture. Thus in a significant number of cases of vasa previa the vessels are torn prior to the rupture of the membranes. This occurred in four of the seven cases of vasa previa reported by Vago and Caspi.[2] Bleeding from lacerated umbilical vessels, with the membranes intact, has also been reported by Mitchell and associates,[5] Vogt,[10] and Benirschke.[11] Vasa previa should also be considered in the differential diagnosis of third-trimester bleeding. Cases where the bleeding has ceased spontaneously and recurred during the seventh and eighth months of pregnancy have been reported.[2] It is postulated that the bleeding ceased because of thrombus formation and recurred secondary to vessel trauma at the time of delivery. In none of the reported cases, however, were the episodes of antepartum bleeding definitely proved to be fetal in origin. Tests to demonstrate the presence of fetal blood should be performed in all cases of antepartum bleeding. This will help clarify the role of vasa previa as a cause of third-trimester bleeding.

4. Bleeding can begin long after the membranes have ruptured. In these cases the initial tear in the membranes does not involve the velamentous vessels. With the onset of labor and cervical dilatation the tear can then extend to involve the vessels.[12]

Diagnosis

Vasa previa is associated with one of the highest fetal mortality rates of any of the complications of pregnancy. Early diagnosis and treatment are essential if this high rate is to be lowered. The most important factor in making the diagnosis is to maintain a high index of suspicion. As can be seen from the varied clinical picture, the diagnosis has to be considered not only in all cases of antepartum and intrapartum bleeding but also in cases of fetal distress in the absence of bleeding. Small amounts of bleeding should not be dismissed. Variations in fetal heart rate need to be evaluated. The combination of scant vaginal bleeding and fetal distress is strongly suggestive of vasa previa.

Several modalities are available to aid in establishing the diagnosis: (1) direct visualization and palpation of the vessels, (2) fetal heart rate monitoring, (3) amnioscopy, and (4) tests for the presence of fetal blood components.

Visualization and palpation of the vessels were reported over a century ago. The difficulty is in distinguishing the velamentous vessels from a presenting umbilical cord. The vessels can be identified by their smaller diameter, lack of mobility, and the absence of a free space around them. Curl and Johnson[13] palpated the artery and demonstrated that pressure on the vessel resulted in bradycardia within 30 seconds. The fetal heart rate returned to normal when the pressure was released. Fetal bradycardia was again noted after abdominal pressure had been exerted to force the vertex into the pelvis. The fetal electrocardiogram is invaluable in assessing the heart rate variability associated with vasa previa.

Barham[8] has advocated rupturing the membranes under direct vision, a procedure he calls "amnioscopic amniotomy." His admonition to "encourage more obstetricians to have a good look at surgical induction of labor, preferably with the amnioscope"[14] is of special interest to this case. The patient was 1 week past term and had been scheduled for admission to the hospital at 7:00 AM that day for elective induction of labor. She was admitted at 6:30 AM, with a history of spontaneous rupture of the membranes an hour earlier. This circumstance relieved her obstetrician of unknowingly contributing to the death of the baby by his elective interference. Amnioscopy should certainly be considered in the evaluation of a patient presenting with antepartum hemorrhage and/or fetal heart rate irregularity or bradycardia.[8] If the patient is bleeding, amnioscopy makes it easier to collect blood for examination and testing.

Since vasa previa involves the loss of fetal and not maternal blood, detection of the constituents of fetal blood is the key in establishing the diagnosis. As far back as 1912, Williamson recommended examination of the blood for normoblasts and nucleated red blood cells. He later abandoned the idea as impractical, since most deliveries were being performed at home. However, a stained blood smear still remains as an extremely valuable tool in the diagnosis of vasa previa. The diagnosis can also be established by demonstrating the presence of fetal hemoglobin. Over the years various tests have been developed, including the use of spectrophotometry, but use of the Apt test, as proposed by Israel[15] in 1961, offers a method which is simple to perform, does not require sophisticated equipment, and provides the results in a few minutes.

In this test 2 to 3 ml of the bloody fluid are mixed with an equal amount of water and centrifuged (2 minutes at 2,000 rpm), and the supernatant is decanted. One part of 0.25N (1%) sodium hydroxide is then mixed with five parts of the decanted pink fluid. Within 2 minutes adult hemoglobin will form an alkaline-hematin compound, resulting in a yellow-brown color. Fetal hemoglobin is alkali resistant, and, in this case, the solution will remain pink. The test may yield a false negative result if the original blood sample contained very little hemoglobin. Sickle cell anemia and thalassemia may give misleading results, since appreciable amounts of fetal hemoglobin are present in the maternal blood in these diseases. A simpler technique for the detection of fetal hemoglobin was described by Ogita[16] in 1976. It can be performed in a few minutes using only chemical reagents. No centrifuge or other equipment is needed. The test can be easily and rapidly performed in the obstetric suite. One drop of the fresh heparinized blood sample is added to five drops of the alkali (0.1N potassium hydroxide) and shaken for 2 minutes. Ten drops of a precipitating solution (400 ml of 50% saturated ammonium sulfate and 1 ml of 10N hydrochloric acid) are added. The mixture is dropped on filter paper with a capillary tube to make a ring approximately 20 mm in diameter. Denatured adult hemoglobin and cell debris will remain at the center. Alkali-resistant fetal hemoglobin will form a colored ring at the periphery.

Treatment

Few situations in obstetrics so dramatically illustrate the need for a correct diagnosis before instituting treatment. Vasa previa is frequently misdiagnosed as abruptio placentae or placenta previa. The management of these conditions generally includes artificial rupture of the membranes, a maneuver which is usually catastrophic in the case of vasa previa.

The treatment of vasa previa is undertaken solely for the fetus. Vasa previa is unique in that it is the only condition in which there is a high fetal mortality rate in the absence of maternal mortality. Treatment is predicated on the fact that the infant, having a total blood volume of approximately 250 cc at term, cannot really tolerate the loss of blood. Immediate delivery is mandatory if the fetus is alive and is to be rescued. If the cervix is fully dilated and vaginal delivery can be accomplished rapidly, this is the method of choice. More often cesarean section is required. Transfusion of the baby may be necessary following delivery, and a pediatrician should be present for the delivery.

A high index of suspicion, familiarity with the clinical features, and utilization of the readily available diagnostic tests are needed if we are to prevent needless deaths from this tragic accident of pregnancy.

Discussion

Dr. William J. Spanos, San Bernardino, California. With a case report of a stillborn term infant Dr. Pent has brought to our attention and consideration a problem neglected on most obstetric services. The problem is not neglected because of lack of concern but because of infrequency of the problem, difficulty in diagnosis, and shortness of time to save the involved infant even if the diagnosis is suspected. The problem is indeed formidable when one considers the instances of vaginal bleeding that occur during labor either as bloody show on entry to the labor room or during the active phase secondary to stretch or minute lacerations of the cervix.

Vasa previa was first described in 1773, yet in over 200 years there are less than 200 cases reported in the literature. We are told that velamentous insertions are not uncommon, ranging from an estimated 1% in normal uncomplicated gestations to approximately 10% in multiple pregnancies.[1] Also in one large series vasa previa was encountered in one of every 2,761 deliveries.[2] If these statistics are accurate, why is vasa previa not recorded more often in the literature? One reason is that a number of cases are undiagnosed. In some cases the diagnosis is not made until after the fetal loss and it has been suggested that few physicians are tempted to report undiagnosed failure.

Each of the papers on this subject in the literature seems to offer a slightly different definition of vasa previa. Dr. Pent gives us a concise, inclusive definition, stating that vasa previa is an anomaly of the umbilical cord insertion in which the umbilical vessels traverse the lower uterine segment presenting in advance of the fetus. With this definition it becomes obvious that bleeding need not be present for the fetus to be at risk as the presenting part may compress the vessels against the pelvic wall and thus cause hypoxia and possible fetal death. Present-day practice of fetal monitoring should alert the obstetrician to hypoxia and thus increase salvage when the problem is only compression of the vasa previa vessels. More important we are reminded by Dr. Pent that the needed tools to make the diagnosis of ruptured fetal vessels and potential rapid fetal death in vasa previa have been available to us for years. The Apt test to distinguish between adult and fetal hemoglobin was described 25 years ago and proposed for use in this problem in 1961 by Israel.[3] Today Dr. Pent has brought to our attention an even more simple test for fetal hemoglobin as proposed by Ogita in 1976. The question now is will we as practicing obstetricians remember this only as an interesting case report or will we insist that our obstetric services have available the chemicals needed and that each bleeding episode be checked for fetal hemoglobin? The reward will be infrequent but very satisfying if an infant that otherwise would have been another stillbirth statistic is saved because of this effort.

Dr. Pent has reported a case in which his results were not as he would have liked but by so doing he brings to our attention a subject that in most obstetric textbooks receives at most two paragraphs but to date has a fetal mortality rate varying from 75% to 100%.

Dr. E. Forrest Boyd, Jr., Los Angeles, California. This is an excellent step in our progress in salvaging fetal lives although it possibly opens a little bit of door temporarily for medical-legal action because, as this becomes known, obviously and more people are going to say, "Well why didn't you save my baby?" even though this is a very rare occurrence. The advent of ultrasound, particularly real-time ultrasound, introduces a possible additional aid, and I wonder if Dr. Pent would want to comment on this use of real-time sonography and possibly following the vessels to their origin. I am personally not that adept at it yet. We have not had it very long, but it is possible to spot the vessels implanted low in the uterus. I think another important facet is to document the actual placenta. How many of us, over the years, have commented, "Well this was a velamentous insertion," and thrown the placenta away. Maybe the pregnancy was not perfectly alright and there might have been something that we did not know about. So I think this might be something to which we can alert our house staff. Needless to say, the value of fetal monitoring and testing for fetal blood is obvious. We spend thousands of dollars looking for babies with phenylketonuria and hypothyroidism and this type of rarity, and yet how much would this cost just to routinely check all bleeding for fetal blood prior to delivery? This might be very valuable. A brief review of our records revealed three cases I shall mention. We examined a 20-year-old primagravid woman at 41½ weeks. The monitors showed severe bradycardia, and a cesarean section was done immediately without any further diagnostic procedures. A 7 pound, 5 ounce baby with Apgar scores of 4 and 6 was delivered, and a low-lying, posterior, velamentous placenta was noted. Another patient, a 30-year-old woman, gravida 4, para 3, at 40 weeks underwent spontaneous vaginal delivery of an 8 pound baby with Apgar scores of 8 and 8; a battledore placenta with a very thin, long portion of it low in the uterus was noted. On the other side of the coin, a third patient, 34 years of age, para 2, was admitted at 36 weeks. She had had decreased fetal movements for 2 days. A nonstress test was performed and showed bradycardia which was timed for 37 minutes. Thirty-seven minutes from the time this was first noted, the baby was delivered by cesarean section. The infant weighed 4 pounds, 14 ounces, and the placenta with velamentous insertion was implanted anteriorly and high in the fundus. The baby died.

This report raised our awareness of a heretofore seemingly unavoidable, but now increasingly preventable tragedy.

Dr. William H. Hindle, Honolulu, Hawaii. I reviewed the experience of Kapiolani Hospital, in Honolulu. Under the I.C.D.A. Code, vasa previa is coded under 663.5, which is velamentous insertion of the umbilical cord. Vasa previa is a subcode of that. I reviewed the delivery records of the last 5 years, 1973 to 1977. During that time there were 26,375 term births at Kapiolani Hospital. I was able to document 22 cases of confirmed velamentous insertion of the umbilical cord. This is a ratio of one case to every 1,199 term deliveries during that time. Of interest in reviewing these 22 cases was the number of additional major obstetric complications in association with velamentous insertion of the cord. There were two sets of twins, two breech presentations, four premature infants (by weight), four cases of fetal distress, one prolapsed cord, one fetus with multiple congenital anomalies, one persistent posterior presentation with mid-forceps delivery, one transverse arrest with delivery by mid-forceps rotation, and one bona fide vasa previa with fetal death. Thus, 17 of the 22 cases (or 77%) had an additional diagnosis of a major obstetric complication. The one case of vasa previa was in a 29-year-old, white woman,

gravida 3, para 2, abortions 0, with an expected date of confinement of August 9, 1973, who was admitted on August 1, 1973. She gave a past history of a 1 hour labor with the previous delivery. She lived more than a half hour's driving time away from the hospital. She and her husband desired Lamaze labor and delivery. After discussion with the couple, they requested elective induction of labor. During her prenatal course, she had a urinary tract infection. During the first trimester, she had an episode of vaginal bleeding with a gush of bright red blood which responded to conservative management with no recurrence of the bleeding. For four months prior to admission, she had had strong Braxton-Hicks contractions. She was very apprehensive about her previous short labor. She had been told by her previous obstetrician, after vaginal examination the day before she was delivered in her previous pregnancy, that the cervix was closed, long, and thick, and that it would probably be at least a week before delivery. This added to her apprehension. On admission the cervix was 3 cm dilated, 75% effaced, and soft with the vertex at the 0 station. The membranes were stripped and were clear to palpation. Amniotomy was followed by a large gush of dark red blood which persisted. Efforts to tamponade the fetal head against the lower uterine segment were carried out. The fetal heart tones became irregular. She developed active uterine contractions. The clinical diagnosis was probable vasa previa. She was delivered by emergency cesarean section, unfortunately of a stillborn infant. Gross inspection and subsequent pathologic examination revealed a long, velamentous insertion of the cord, with rupture of a velamentous vessel associated with hemorrhage and a pale stillborn fetus. Of further interest was the umbilical cord which had an anomaly, only two vessels. Thus, of the confirmed coded diagnoses of velamentous insertion of the umbilical cord at Kapiolani Hospital, 77% had additional major obstetric complications. I wonder if, in his review of the literature, Dr. Pent found note of this apparent association.

DR. LOUIS BARTOLUCCI, San Francisco, California. By no means intending to answer the question asked of Dr. Pent, I would like to comment on the fact that ultrasound, although not able to show directly "vasa previa," should routinely demonstrate the placental implantation and its limits so that the confusing entity of placenta previa, partial or total, be eliminated. I think that every time painless third-trimester or intrapartum bleeding is presented, an ultrasound scan should either introduce or reinforce the suspicion of "vasa previa."

DR. PENT (Closing). I have had no personal experience with the Ogita test, having discontinued the practice of obstetrics long before he described his test. However, I am firmly convinced that it can be performed by any trained paramedical personnel. In one of my lighter moments, this summer, I considered having a slide showing a very sophisticated piece of equipment, with lots of dials, lights, and buzzers, which would be marketed for $5,000 or $10,000. Then every hospital delivery unit would have one. Behind the unit I was going to have a chimpanzee, sitting there with the two reagents, performing the test.

Dr. Bartolucci has answered Dr. Boyd's question relating to ultrasound. Although the umbilical artery and veins have been distinguished by ultrasound as they course through the umbilical cord, I believe that there would be difficulty in identifying the vessels deep down in the bony pelvis.

In reply to Dr. Hindle, velamentous insertion is associated, in a significant percentage of cases, with the absence of one umbilical artery and with a higher incidence of congenital anomalies. The baby in this case report was found to have a horseshoe kidney at autopsy.

Pregnancy complicated by diabetes mellitus in private practice: A review of ten years

RAYMOND S. CORWIN, M.D.
Portland, Oregon

Two hundred private diabetic patients delivered of their infants (202) in a private hospital were evaluated for a 10 year study period (1968 to 1977). There were no maternal deaths. An 88% overall survival rate of viable infants compared favorably with that of other reported series. Analysis of each of the 10 years demonstrated marked changes in management and consequent changes in fetal survival, morbidity, and mortality rates. No neonatal deaths occurred during the last 3 years of the study period and the mortality rate in viable infants was 6.8%. There has been no significant temporal change in the incidence of toxemia or hydramnios. Fifteen stillbirths and ten neonatal deaths were analyzed to identify significant factors or parameters. Attention is directed to sex ratios (male:female) of 3:1 for stillbirths and 3:2 for infants affected with respiratory distress syndrome. Conservative use of accessory testing and antepartum hospitalization was obvious. The question of the necessity for expensive and intensive regimented institutional management is addressed. A minimum management regimen is proposed to be used in conjunction with the private obstetrician's clinical judgment and expertise. (AM. J. OBSTET. GYNECOL. 134:156, 1979.)

THE PAST TEN YEARS encompass major advancements in assessment of fetal pulmonary maturity and fetoplacental well-being. Though these tests are not without their vagaries of interpretation, they have significantly affected management of the diabetic pregnancy. It is the purpose of this study to evaluate the management and outcome of pregnancies complicated by diabetes mellitus in private practice during a 10 year period.

Material and methods

The patients included all pregnancies of 20 weeks' gestational age or greater complicated by diabetes mellitus, delivered at Good Samaritan Hospital and Medical Center, Portland, during the years 1968 through 1977. The 18 bed Diabetic Unit of the hospital is unique in this area, offering classes in self-management and affording a less expensive alternative to hospitalization for diabetic control. We are fortunate to have a group of diabetologists, located near the hospital, who have been instrumental in the development of this unit and who have provided diabetic care for 85% of the patients in this study, exclusive of Class A patients. Many different Board-certified or Board-qualified obstetricians rendered care. A variety of pediatricians were involved in care of the newborn infant; however, one pediatric group accounted for 76% of this care.

From the Good Samaritan Hospital and Medical Center.

Presented by invitation at the Forty-fifth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Gleneden Beach, Oregon, September 26-30, 1978.

Results

During the period January 1, 1968, through December 31, 1977, there were 19,673 deliveries at Good Samaritan Hospital and Medical Center. Two hundred of these pregnancies were complicated by diabetes, for an incidence of 1.02%. Of those recorded, 97 infants were male and 93 were female. Significant congenital anomalies occurred in nine infants (4.5%). The average maternal age was 25.8 years with a range from 15 to 39 years. The averages of gravidity and parity were 2.35 and 0.96, respectively. There were 54 (28.4%) primagravid women. No significant year-to-year difference was noted for maternal age, gravidity, or parity.

Table I classifies the material according to the criteria of White and associates.[1]

One hundred thirty-eight pregnancies (69%) were delivered by cesarean section. Excluding Class A patients, 117 (79.6%) were delivered by cesarean section. Table II compares delivery modality of the study group with all deliveries during the same period. Diabetic indications dictated primary cesarean section in 63 patients (31.5%). Primary cesarean sections were performed in 21 cases (10.5%) for other indications.

1976	2	5.4			2	5.4
1977	2	9.1			2	9.1

Repeat cesarean sections were performed in 54 patients (27%). There was no significant change in rates from year to year.

Complications of pregnancy included toxemia in 33 patients, hydramnios in 32 patients, premature rupture of the membranes in 13 patients, and premature labor with intact membranes in 15 patients. Analysis of cases with these complications did not demonstrate any year-to-year change.

The overall survival rate of viable (28 weeks or greater) infants was 88.1%. One stillborn infant in 1969 at 24 weeks' gestation was the only infant in the study born at less than 28 weeks. Table III relates White's classification to fetal loss. The overall perinatal mortality rate was 12.4%. Considering only Class B through R pregnancies the perinatal mortality rate was 14.8%. Table IV relates fetal loss to year. A definite decrease in neonatal mortality rate is noted with no neonatal deaths occurring during the last 4 years.

Stillbirths. The results of an in-depth analysis of the 15 stillborn infants are presented in Table V. The sex ratio of male to female infants is 3:1; however, this difference is not statistically significant. Toxemia was present in almost half of the cases. All patients with hydramnios also demonstrated toxemia. The three infants listed as having evidence of pulmonary maturity had lecithin-sphingomyelin ratios of 4:1, 2.5:1, and 2.8:1, respectively. The time intervals from amniocentesis to fetal death were 6 days, 4 days, and 1 day, respectively. One of the two congenital anomalies was severe anencephaly. The other was diagnosed at autopsy as stillbirth secondary to true knot in the cord.

Neonatal death. Table VI summarizes an in-depth analysis of the 10 neonatal deaths. All infants died of hyaline membrane disease diagnosed either at autopsy or by clinical course of respiratory distress. Two cases admitted in advanced premature labor were delivered vaginally. Premature labor dictated delivery time in three cases. Delivery of the remaining seven cases, occurring prior to 1972, was timed empirically based on past obstetric history and clinical evaluation, including hydramnios in four cases and toxemia in one case. Fetography performed in two cases did not demonstrate distal femoral epiphyses. No other tests of fetal well-being or fetal maturity were reported.

Respiratory distress syndrome (RDS). The incidence of RDS from year to year fluctuates markedly between 10% and 43% but does not demonstrate any statistically significant change. The severity of distress has decreased, resulting in no neonatal deaths since 1973. The sex ratio of affected infants was 3 male to 2 female. Of 52 infants, 31 were male and 19 were fe-

Table VII. Average number of days in hospital

	All Classes	*Classes B to R*
Maternal:		
For delivery	6.1	6.8
Including antepartum admissions	7.2	8.3
Neonatal:		
At Good Samaritan	6.8	7.6
Including transfers to University of Oregon Medical Center	7.3	8.3

male, and in two cases sex was not recorded. These deviations are not statistically significant. Amniocentesis for fetal pulmonary maturation was utilized in 10 of the 52 pregnancies. X-ray films to determine fetal age were obtained in 13 cases. In 29 pregnancies, no tests for fetal maturity were performed. Delivery was effected because of premature labor in nine cases and premature rupture of the membranes in six cases.

Length of hospital stay. Table VII summarizes maternal and neonatal length of hospital stay, excluding stillbirths and neonatal deaths. In 38 diabetic pregnancies, Classes B through R, a total of 203 additional antepartum hospital days were required for diabetic control or complications of pregnancy. Six infants transferred to the University of Oregon Health Sciences Center Neonatal Intensive Care Unit required a total of 82 additional hospital days.

Table VIII compares fetal outcome and protocol for Class B through R pregnancies at Good Samaritan Hospital and Medical Center for the 10 year study period and for the last 3 years with other similar studies.

Comment

The management philosophy of the private practitioners in this study contrasts sharply with the recommended protocols of other studies.[2–7] A definite interval between procedure availability and procedure utilization reflects the obstetricians "wait and see" attitude. Clinical experience, judgment, and concern for patient cost result in limited use of ancillary procedures after their acceptance.

Antepartum hospitalization was held to a minimum, averaging 7.2 days in this study compared to several weeks in others. Goldstein and associates[5] contend that costs of increased maternal hospitalization (average 28 days) are offset by decreased neonatal hospitalization (average 4 days in intensive care and 8 days in nursery). That contention is not supported by the average hospital stay of 7.3 days for infants in this study. Experienced clinical judgment and expertise can minimize ancillary procedures and hospitalization without compromising patient care or fetal well-being.

Many studies since 1949[8] have demonstrated the higher prenatal mortality rate of the male sex. The sex ratios (male:female) of 3:1 among the stillbirths and 3:2 for infants affected by RDS were not statistically significant; however, they should be noted for further study in larger numbers. Sex determination may be warranted for consideration in the future.

One of the stillborn infants, delivered of a mother with Class A diabetes, exemplifies the problem of physician awareness and antenatal diagnosis in this class. Though four of this patient's close relatives, including her mother, were diabetic, the diagnosis of diabetes was not made until the first postpartum day. Lack of definite diagnosis of Class A diabetes is evident in the incidence of 26.5% (53 cases) in this study as compared to an expected incidence of 80% (588 cases).[9]

The lack of decrease in stillbirth rates is disappointing. The average gestational age of 34.7 weeks at this

occurrence may indicate the need to begin routine evaluations of fetal well-being earlier in gestation.

A minimum protocol is proposed for Class B through R diabetic pregnancies in private practice to minimize ancillary testing without compromise to patient care. At 18 weeks, prior to development of macrosomia, ultrasonography will confirm gestational age. At 28 weeks, ultrasonography evaluates fetal macrosomia, placental edema, and placental localization for future amniocentesis. Weekly contraction stress tests or nonstress tests should begin at 32 weeks. After 34 weeks, serum estriol determinations are performed two times weekly. At 37 weeks amniocentesis is performed, utilizing ultrasonography if necessary. Fetal pulmonary maturation should be determined by more than one parameter, such as lecithin-sphingomyelin ratio and palmitic acid. Delivery should be effected without delay when evidence of fetal pulmonary maturity is present. Clinical judgment should dictate deviation from protocol with complications of pregnancy or diabetes. Without evidence of progression of disease or complications, Class A diabetic pregnancies should be managed expectantly and conservatively and delivered at term.

Discussion

Dr. Leon P. Fox, San Jose, California. Dr. Corwin has ably presented in retrospect a significant experience in the management of pregnancy complicated by diabetes mellitus in a private-practice setting. In my opinion this depicts fairly accurately the current situation in most such environments. It certainly is similar to my community's efforts. His data indicate that stillbirths continue at the same rate though neonatal deaths recently have been eliminated. Comparative statistics gathered at high-risk obstetric centers indicate much better results. The bottom line in diabetic pregnancies is ideally to erase all perinatal deaths and this currently appears to depend upon superior expensive antenatal care of these patients. Dr. Corwin in an effort to improve results has now proposed a standard protocol to his associates which no doubt will be effective.

The name of the game is early diagnosis; accurate determinations of fetal age in the second trimester; continuous monitoring of blood sugar levels on a

Table I. Pertinent comparable costs—1940 and 1978

monthly basis; team approach to meticulous therapy, utilizing obstetrically oriented diabetologists, currently knowledgeable obstetricians, and consulting perinatologists-neonatologists in a facility with immediately available laboratory technology and appropriate monitoring equipment in all parameters; and, last but not least, a developed protocol for complete education and counseling of the patient throughout her pregnancy.

Although all of us are continually interested in cost control in the care of these and other patients, cost must not be the reason for withholding these absolutely necessary services from the pregnant diabetic patient. Diabetes has long been recognized as a "rich man's disease" and will continue to be so. Recent estimates of the increased expense of ideal high-risk care of these diabetic patients is approximately $6,500 or more. The challenge, therefore, is to seek ways of providing this same care at a lower cost. Schneider in Memphis has done something about this, and in as yet unpublished material has described a group of patients managed in a high-risk public hospital setting on a carefully controlled out patient basis. Utilizing the protocol mentioned with some changes, all patients are screened for diabetes clinically as usual early in the second trimester, depending upon the blood sugar level 2 hours after a meal. The diabetic patients are classified and placed on a continuing, comprehensive educational and counseling program. This includes instruction in self-testing of postprandial blood sugar level each month in Class A patients and three times daily or more in insulin-dependent patients by use of the reflectometer.

Early in the second trimester clinical and sonographic efforts are made to determine fetal age. This is confirmed after the twenty-eighth week. From the thirty-second week patients are seen on a weekly basis with close attention to fetal well-being and, of course, diabetic control. Nonstress testing at home and in the outpatient department is charted and depended upon. If the fetal age has become apparently confirmed, at 38 weeks a lecithin/sphingomyelin (L/S) ratio is obtained and a phosphatidylglycerol test is done. If the L/S ratio is above 2 and phosphatidylglycerol is present there will be no RDS problem and delivery is carried out in the indicated manner. All newborn infants must have intensive care for 2 or 3 days or more.

Only sick patients are hospitalized and of course estriol determinations, oxytocin challenge tests, and other appropriate tests are done. Dr. Corwin's perinatal loss in some 108 patients averaging 7.1 days of hospitalization was 37/1,000, there being one stillbirth and three neonatal deaths.

The hospitalization costs compare with Dr. Corwin's data and the perinatal results are similar to the long-term hospital stay data presented. Dr. Schneider has stated that "A difference to be a difference must make a difference," and certainly this program does so.

I believe all insulin-dependent mothers should be delivered in a high-risk maternity center by their own obstetricians who can make use of all the facilities necessary to provide the intensive care that is imperative to the mother and newborn infant.

I would like to say just a word about health care costs. Our politicians and other propagandists get carried away in their selective separation of health care costs from the general economy trends and, with you, I become very irritated by these tactics to force us into government control when everyone knows that everything done by government is always the most expensive. In 1940, when my first child was born, obstetricians were charging $75 to $100 for total usual care and $150 if a cesarean section was done. The hospital bill was $50 for 10 days. My automobile cost $1,200 and my home $13,000. Today, in the same area, the obstetrician averages $650 for usual care and $900 for total care plus cesarean section. A comparable automobile now costs $13,000. The usual 2 to 3 day hospital stay is about $1,500, including anesthesia, mostly due to salaries and equipment. If the stay should reach 10 days the total would be $3,500 and the same home now costs $65,000. Inflation has made our numbers meaningless and our currency valueless. Table I indicates the cost changes during the past 38 years.

During this time period the percentage of perinatal deaths in diabetic patients has decreased sevenfold and the average income has increased thirteenfold. When I hear a patient complain about the $6,500 extra costs for the care in her diabetic pregnancy I ask her what she paid for her automobile and she is reminded promptly of her priorities. We still continue to save babies in better conditions and we will continue to devise methods of cost control if we are permitted to do so.

Dr. Robert H. Gregg, Covina, California. In reviewing the literature and Dr. Corwin's article, I would like to add one other aspect to the equation of diabetes complicated by pregnancy leading to the bottom line. Several of us have had brief conversations, here at Salishan, on the future social, cultural, and medical ramifications of scientific progress. As far as we know, exclusive of Divine Providence, man is the only living thing who can, and has been able to, *by choice* seek the cause and effect of things and, again through choice, to change his environment, both internal and external, and particularly in this century to begin to effect con-

trol over his internal milieu. On the surface, this may seem like a very basic human need and the thing to do. Of course this is what science and the practice of medicine are all about, that is, to treat the infirmed, prevent disability and disease, and promote health and well-being, and indeed, in the long run, maybe to engineer a so-called "super human being" and even a "super race," which was attempted about 40 years ago. But in our mad dash to overcome and alleviate the obvious need, are we taking into consideration the natural and biological balances that are necessary to sustain, maintain, and perpetuate the species on this earth? Are we asking ourselves the very serious, more significant and poignant questions, to what extent should the diabetic patient in this instance have the same benefits of normal life expectancy, health and happiness, children, and so forth? Should they not be part of the human race also? But in the final analysis where do our efforts stop? How far should they go? Should they stop at all?

DR. CORWIN (Closing). I heartily agree with everything Dr. Fox said.

I am not quite sure how to answer Dr. Gregg. This has been an age-old argument, philosophical mostly, regarding the eugenic considerations of diabetes. I think it probably is the same with any other disease state having genetic implications. As of this juncture, in any case, I believe we are charged with the responsibility to do the best we can with any pregnancy, regardless of the nature of the pathologic or unusual state the patient may have, assuming the patient understands the inherent risks, hazards, and future consequences. I would like to emphasize one thing that Dr. Fox brought out—and that I did not emphasize in my paper—I am still, and I believe all of us are, a firm believer in the team approach to the diabetic pregnancy. I feel it is extremely important to have the cooperation of three groups—pediatricians, obstetricians, and internists (ideally diabetologists). Apparent suboptimal utilization of ancillary testing in our institution may be the result of suboptimal medical records. All of you, having done research involving only the medical records, appreciate the fact that medical records are often incomplete—excepting your own.

Urinary tract endometriosis: Enigmas in diagnosis and management

J. GEORGE MOORE
LESTER T. HIBBARD
WILLIAM A. GROWDON
BARRY S. SCHIFRIN
Los Angeles, California

The diagnosis and management of endometriosis presents several enigmas. This review, of eight patients with endometriosis involving the urinary tract, from three large clinical services in the City of Los Angeles, highlights some very difficult problems. Not only diagnostic errors but also inappropriate conservatism and inadequate surveillance have led to compromised function, resection, and/or destruction of the kidneys, ureters, or bladder. The series indicates those findings which are likely to result in urinary tract destruction and points out those clinical situations in which delays or conservative management must be undertaken only with pressing indications and then only with continued and careful surveillance.

ENDOMETRIOSIS with significant involvement of the urinary tract is not particularly uncommon. Involvement of the urinary bladder is more common, but associated ureteral obstruction presents a more serious threat to renal function. The magnitude of this threat has become apparent only in recent years. In 1960, a review of the world literature uncovered only 15 reported cases of endometriotic obstruction of the ureter. By 1965, Kerr's[2] review brought the total up to 47 and, in 1974, Durfee, in discussing Langmade's[3] report of five cases before this Society, reported 85 such cases in the literature. Reports since then[4–9] and the present series bring the total to over 100 patients with ureteral obstruction caused by endometriosis. It is quite probable that there is a far larger number unreported and even unrecognized.

In the largest series of endometriosis with ureteral obstruction (11 cases collected over a 40 year period), Stanley and associates[10] emphasized that the relative paucity of specific diagnostic symptoms or physical signs augured against an early appreciation of a threat to the urinary tract. Catamenia-associated symptoms and even microscopic hematuria represent diagnostic exceptions. Generally excretory urograms taken in the investigation of backache, headache, hypertension, or a pelvic mass bring a suspicion of endometriosis into focus. Occasionally cystoscopy, retrograde ureteropyelograms, and even laparoscopy fail to indicate endometriosis. The present report demonstrates the importance of paying careful attention to the uterosacral ligaments in evaluating ureteral obstruction in women of menstrual age. It is apparent that when the cardinal and the uterosacral ligaments are involved with endometriosis, the ureters and kidneys are at risk and careful surveillance is in order. As indicated by Kerr,[2] Meigs emphasized this point four decades ago.

Most authors[2, 3] indicate that prudent management of ureteral obstruction from endometriosis includes relief of obstruction (ureteral lysis, implantation, or diversion), resection of endometriosis, and surgical castration (bilateral oophorectomy and hysterectomy). They emphasize that inordinate delays and what Green[11] terms "conservationistic" surgery generally lead to further problems. Such optimal management presents no great conflict if the patient is multiparous and over 40 years of age. The conflicts arise when the

patient is in her twenties and strongly desires more children. In the present series an unusually young group of women, highly desirous of maintaining fertility, posed some difficult problems.

Clinical material

Patient records of the Cedars-Sinai, Los Angeles County–University of Southern California, and the University of California, Los Angeles, Medical Centers were searched for patients operated upon for endometriosis with ureteral obstruction. Eight such patients, operated upon in the past 8 years, are listed in Table I. Seven were operated upon at the University of California, Los Angeles, Hospital. The record search extending back to 1965 revealed no patients operated upon for this condition at Cedars-Sinai and only one (Case No. 4) at the Los Angeles County–University of Southern California Hospital. One of the patients operated upon at the University of California, Los Angeles, Hospital (Case No. 5) had previously had a laparoscopic exploration at Cedars-Sinai.

Of the eight patients, two (Cases 1 and 7) were over 40 years of age when operated upon and were the only

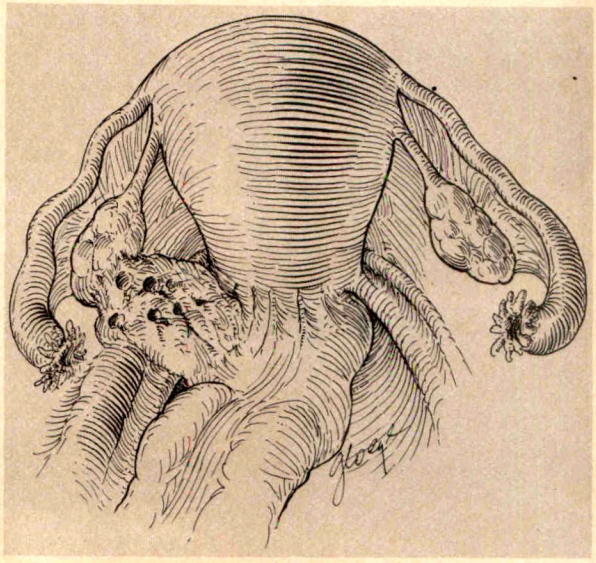

Fig. 2. Operative findings in Case No. 1, showing relatively restricted extent of endometriosis involving the left ovary and uterosacral ligament. The proximal ureter, as opposed to that in Case No. 5, is widely dilated.

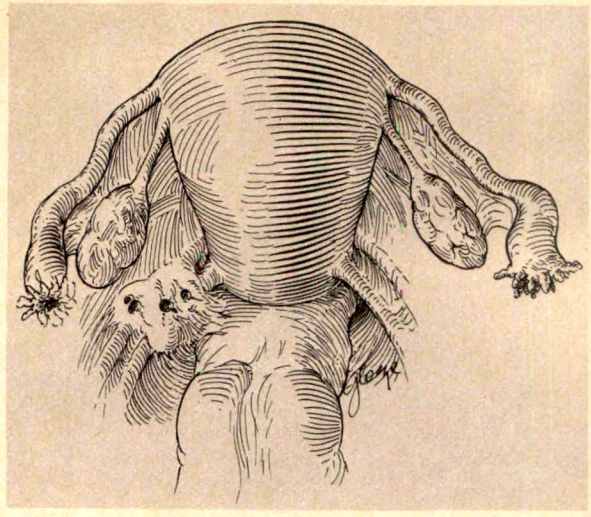

Fig. 3. Operative findings in Case No. 5. Note that both ovaries and tubes are not involved. The endometrioma, not impressive on the surface, extended deeply retroperitoneal and was confined to the left uterosacral ligament, the cardinal ligament fully occupying the "web" and the lateral wall of the rectosigmoid colon, and completely obstructing the distal left ureter. Since the kidney was no longer functional the ureter was not distended.

multiparous patients in the group. The next oldest patient (Case No. 5) was 33, had one child, was divorced, and hoped for remarriage and more children. The others (Cases 2, 3, 4, 6, and 8) were nulliparous and their ages ranged from 32 down to 21 years.

Case No. 1 illustrates very well the diagnostic prob-

Table I. Clinical data in eight cases of endometriosis

Case No.	*Year*	*History and diagnostic appraisal*
1 (age 43, gravida 2, para 2)	1969	Backache, negative myelogram
	1970	Dysmenorrhea and postcoital back pain. Endometriosis suspected. Progestational suppression
	1971 (UCLA)	3-4 cm mass at base of left broad ligament. Intravenous pyelograms showed left hydronephrosis
2 (age 30, gravida 0)	1969	Dysmenorrhea and infertility, 3 yr. Resection of rt. ovarian endometrioma
	1970	Progressive dysmenorrhea and dyschezia
	1971 (UCLA)	8 cm left adnexal mass. Intravenous pyelograms showed obstruction distal to left ureter
3 (age 32, gravida 0)	1967-73	Oral contraception. Blood pressure 120/70
	1974	Dysmenorrhea and premenstrual dysuria
	1975 (Indiana U.)	Intravenous pyelograms showed medial displacement of both ureters. Laparoscopy showed extensive pelvic endometriosis. Renal scans showed hydronephrosis, hydroureter, and delayed excretion. Progestational suppression, followed by resolution of hydronephrosis
	1976 (UCLA)	Dysmenorrhea and recurrence of lower abd. pain on cessation of menstrual suppression. Blood pressure 130/90
4 (age 25, gravida 0)	1977 (USC)	2 yr. history of flank pain, hematuria, and dysmenorrhea, 2 mo. history of dizzy spells and hypertension. Pelvic examination showed bluish cyst in right fornix, fixed retroversion of uterus, uterosacral nodularity. Blood pressure 170/120, 4+ albuminuria, microscopic hematuria, creatinine 1.3 mg/100 ml, aldosterone 24 mcg/24 hr. Aortograms showed 1.5 mm of right renal cortex with marked hydronephrosis
5 (age 33, divorced, gravida 4, para 1, 3 therapeutic abortions)	1977 (Cedars-Sinai)	5 mo. history of headache and hypertension. Intravenous pyelogram showed delayed left renal function and hydronephrosis. Blood pressure 180/110. Minimal uptake of left kidney on renal scan. Laparoscopy showed no endometriosis. Arteriogram showed minimal left renal cortex visualized.
	1977 (UCLA)	Blood pressure 110/65 (asymptomatic except for dyschezia and dyspareunia). Pelvic examination showed 4-5 cm tender, fixed, firm mass to left of and posterior to the uterus and cervix
6 (age 26, gravida 0)	1978 (UCLA)	1 yr. history of progressive dysmenorrhea with LLQ abdominal pain despite oral contraceptives. 3-4 mo. of dysuria with menses. Pelvic examination showed tender, nodular uterosacral ligaments with 2 by 6 cm nodule anterior to rectum, 3 by 5 cm irregular, firm mass anterior to uterus. Pelvic ultrasound showed mass impinging on bladder. Intravenous pyelograms showed filling defect in bladder and right hydronephrosis
7 (age 44, gravida 3, para 2)	1962 (Philippines)	RLQ pain. RSO for endometrioma. Progestational suppression of menses
	1965	Resection of left ovarian endometrioma
	1967-1974	Two term births
	1977	RLQ pain and intestinal obstruction. Resection of endometriosis, segmental small bowel resection, appendectomy
	(Feb.) 1978 (Philippines)	TAH and LSO (no menopausal symptoms)
	(Aug.) 1978 (UCLA)	RLQ and RUQ abdominal pain. FSH not elevated. Sonogram showed 9 by 9 cm right pelvic cyst. Intravenous pyelogram showed right hydronephrosis
8 (age 21, gravida 0)	1975 (UCLA)	Dysmenorrhea despite oral contraceptives. Pelvic examination showed tender, nodular right uterosacral ligament. Laparoscopic biopsy showed endometriosis
	1976 and 1977	3-4 cm tender mass in area of right uterosacral ligament
	1978	Angulation, medial displacement, and impaired drainage of right ureter

TAH = Total abdominal hysterectomy; BSO = bilateral salpingo-oophorectomy; LSO = left salpingo-oophorectomy; LLQ = left lower quadrant; RLQ = right lower quadrant; RSO = right salpingo-oophorectomy; RUQ = right upper quadrant; FSH = follicle-stimulating hormone.

lems. The patient suffered for 2 years with severe back pain and was investigated thoroughly for discogenic disease, including myelograms before the onset of dysmenorrhea, and a mass in the region of the left uterosacral ligament finally led to the presumptive diagnosis of endometriosis. Intravenous urography revealed massive left hydronephrosis and retrograde pyeloureterography confirmed the marked stenosis of the ureter 2 to 4 cm from the vesical orifice with marked ureteral dilatation above the stenosis (Fig. 1). At operation a single, solid 4 cm endometrioma involving the left ovary and uterosacral ligament engulfed the left ureter with a tensely dilated ureter superior to the mass (Fig. 2). At her age and parity management presented no problem. The endometrioma was resected and total hysterectomy, bilateral salpingo-oopho-

Operative findings	*Operative procedure*	*Postoperative course*
Endometriosis restricted to left ovary and uterosacral ligament, with massively dilated ureter. Stenosis 2-3 cm above ureterovesical junction	TAH and BSO. Resection of distal third of left ureter. Left ureteroneocystotomy	Normal renal function. Slight urinary reflux. No problems up to 1978
Endometriosis of left ovary and uterosacral ligament	TAH and LSO. Left ureteral lysis	Normal intravenous pyelogram. Asymptomatic with estrogens up to 1978
Retrograde pyelograms showed medial deviation of right ureter with scarred encasement from 4 to 8 cm from ureterovesical junction. Extensive endometriosis involving both ovaries, uterosacral ligaments, rectosigmoid colon, bilateral periureteral involvement, appendiceal involvement	Bilateral ureteral lysis. TAH and BSO	Uneventful postoperative course. Blood pressure 120/70. Norlutate suppression. Death 4 mo. postoperatively in auto/train accident
Endometriosis of ovaries and uterosacral ligaments. Obstructed right ureter 2 cm from ureterovesical junction	TAH and BSO. Right ureteroneocystotomy	Uneventful postoperative course. Intravenous pyelogram showed atrophy of right kidney. Blood pressure 120/80
Isolated focus of endometriosis involving base of left broad ligament, left uterosacral ligament, and left lateral portion of rectosigmoid colon—largely extraperitoneal with puckering of overlying peritoneum. Frozen section revealed endometriosis obstructing left ureter. Uterus, tubes, and ovaries not involved	Resection of left kidney and ureter. Resection of left parametrium ("the web") with left uterosacral ligament and wedge resection of left lateral wall of rectosigmoid colon. Left uterine vessels removed but not left ovarian ligament. Left round ligament suspension of uterus. Appendectomy and curettage	Uneventful postoperative course. Asymptomatic. Uses diaphragm
Cystoscopy showed 2-3 cm mass in right superolateral aspect of bladder wall. Urothelium intact. Large focus of endometriosis involving omentum, wall of transverse colon, wall of bladder, and anterior uterine peritoneal surface	Open resection of bladder wall, omental resection, segmental resection of transverse colon. Right ureteral lysis. Presacral neurectomy	Uneventful postoperative course
Extensive endometriosis with endometrioma in right pelvis involving the right ureter, right base of urinary bladder and wall of rectosigmoid colon	Resection of right ovarian endometrioma, proximal right ureterostomy with placement of ureteral catheter, ureteral lysis, resection of endometriosis of bladder wall and rectosigmoid colon	Uneventful, with removal of ureteral stint on second postoperative day and suprapubic catheter on sixth postoperative day. Discharged with progestational menstrual suppression
3-4 cm endometrioma of right uterosacral ligament	Right ureterolysis, resection of endometrioma of uterosacral ligaments	Uneventful postoperative course

rectomy, appendectomy, and left uteroneocystotomy were performed. In the 8 years of follow-up she has had no problems, intravenous urography is normal and there is very slight left ureteral reflux.

In Case 2, after several years of severe dysmenorrhea and infertility, the patient, at the age of 28, underwent right salpingo-oophorectomy for an endometrioma of the right ovary. After two additional years of progressive dysmenorrhea and dyschezia, she developed a cystic left adnexal mass. Intravenous urography showed partial obstruction of the distal left ureter. At surgery she was noted to have extensive endometriosis of the left ovary, left uterosacral ligament, and the posterior aspect of the bladder. Because of the disabling symptoms and the extensive distribution of the endometriosis, a right salpingo-oophorectomy, total hysterectomy, and ureteral lysis were performed along with resection of all grossly apparent endometriosis.

Case No. 3 had previously been reported[5] as demonstrating the regression of ureteral obstruction with

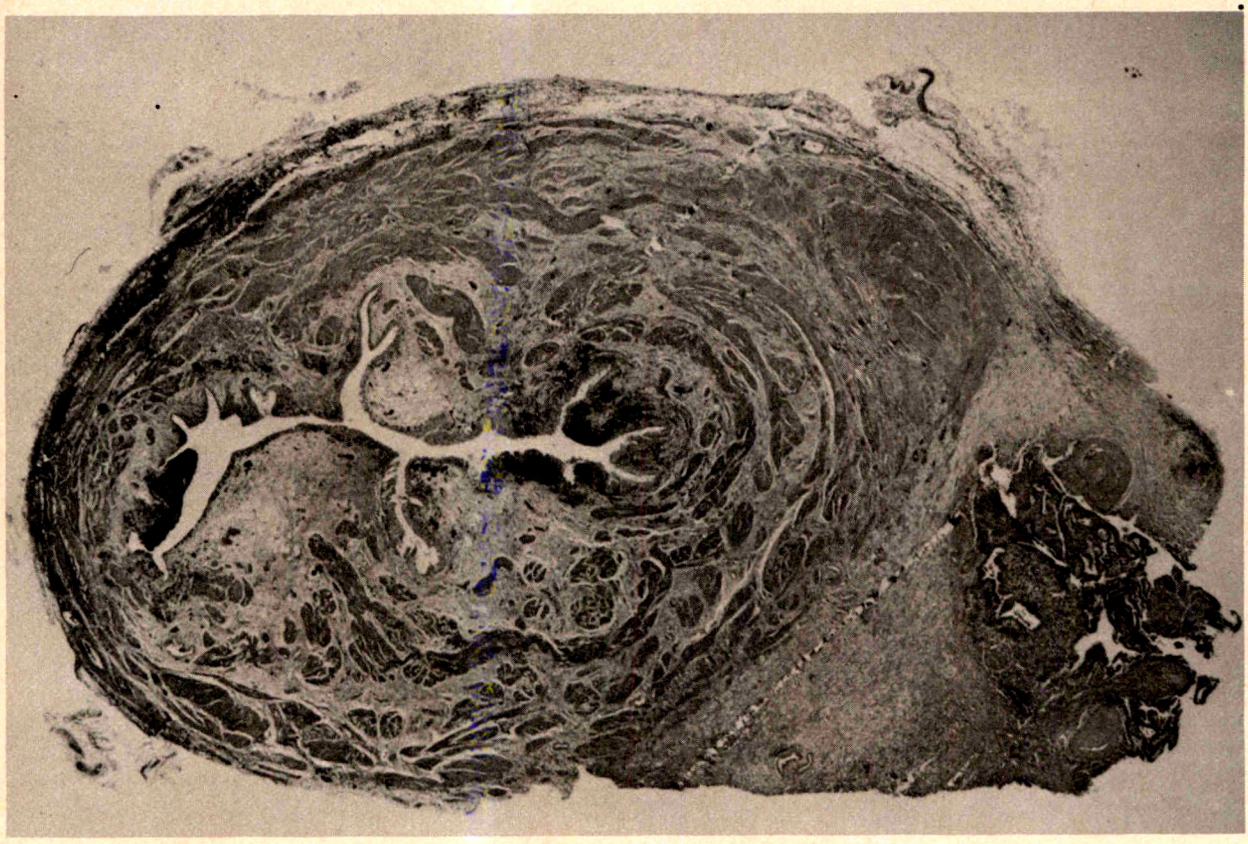

Fig. 4. Area of endometriosis beside collapsed ureter (obstructed distally) in Case No. 5. Kidney was nonfunctional.

progestational suppression of menses. The following year, with return of symptoms and the development of hydronephrosis on the opposite side, and despite her nulliparity, she underwent bilateral salpingo-oophorectomy, total hysterectomy, appendectomy, resection of endometriomas, and bilateral ureteral lysis. Postoperatively she had normal ureters by intravenous pyelograms with uneventful follow-up to 4 months, when she was killed in an accident.

In Case No. 4, the patient was 25 years old and nulliparous, with symptoms and findings suggestive of extensive endometriosis and right renal cortical destruction. A thorough study of renal function indicated minimal function of the right kidney. Because of extensive endometriosis bilateral salpingo-oophorectomy, total abdominal hysterectomy, resection of endometriomas, and a right ureteroneocystotomy were done. Six weeks postoperatively the blood pressure returned to normal and the renal study showed atrophy of the right kidney with a patent right ureter.

In Case No. 5 the patient presented with a 1 year history of left pelvic pain, dyspareunia, and dyschezia and 5 months of headache and hypertension. Symptoms and findings were those of left renal cortical destruction and the diagnosis of endometriosis could not be made even on laparoscopy. During a period of observation the headache and hypertension disappeared but dyschezia and dyspareuia persisted. A firm mass was noted at the base of the left broad ligament and left uterosacral ligament. At operation a single 4 cm solid retroperitoneal mass engulfed and completely obstructed the left ureter (Fig. 3). With complete destruction of the left renal cortex the ureter was no longer dilated proximal to the obstruction. She was subjected to a left ureteronephrectomy including resection of the endometrioma (Fig. 4), a segment of the rectocolonic wall, the left uterosacral ligament, the left cardinal ligament, and the left uterine blood vessels. Because of the restricted extent of the endometriosis and her strong desire for maintaining fertility, the ovaries, tubes, and uterus were left intact. Obviously, she is scheduled for careful periodic surveillance.

In Case No. 6, the patient was a 26-year-old nulligravid woman with a 6 year history of dysmenorrhea

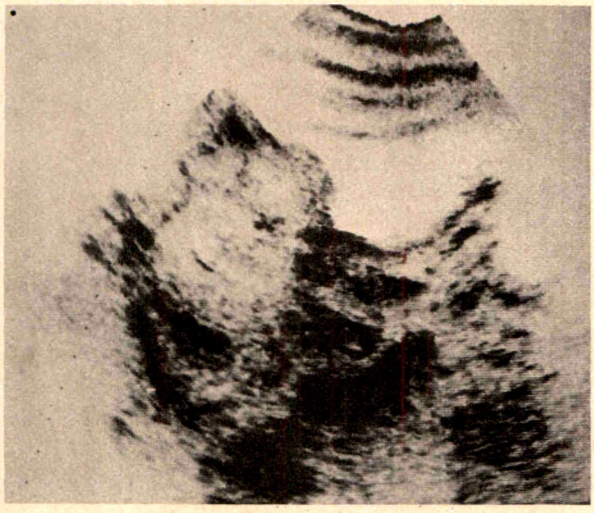

Fig. 5. Midline sagittal sonogram in Case No. 6 showing mass anterior to uterus involving wall of bladder.

and 3 to 4 months of catemenial dysuria. On examination she was found to have a mass in the region of the right uterosacral ligament and another mass anterior to the uterus. Sonography (Fig. 5), intravenous urography (Fig. 6), and cystoscopy were helpful in delineating the problem. Operative exploration revealed that the tubes and ovaries were not involved (Figs. 7A and 7B) and, in view of her strong desire for children, the endometriosis, though moderately extensive and involving the transverse colon, the bladder, and the uterine wall, was resected with repair of the involved structures and ureteral lysis. This does not represent the safest management of endometriosis of this extent and careful surveillance is mandatory.

Case No. 7 represents a serious urologic problem resulting from inadequate resection of endometriomas in a multiparous woman in her 40's. Fig. 8, *A* and *B*, illustrates the marked ureteral obstruction. Quite obviously residual ovarian tissue was left since a corpus luteum was found in the tissue containing residual endometriosis. On this occasion it was necessary to perform a right ureterostomy in order to ensure an adequate ureteral lumen during the ureteral lysis. Although the initial postoperative studies show a normal urinary tract, sufficient time has not elapsed to ensure integrity of the right ureter.

Case No. 8 indicates the need for careful continued surveillance of patients with endometriosis of the uterosacral ligament. Two years prior to exploratory surgery, this 21-year-old nulligravid woman had endometriosis confirmed at laparoscopic biopsy of the right uterosacral ligament. The ovaries were not involved and no peritoneal endometriosis could be seen

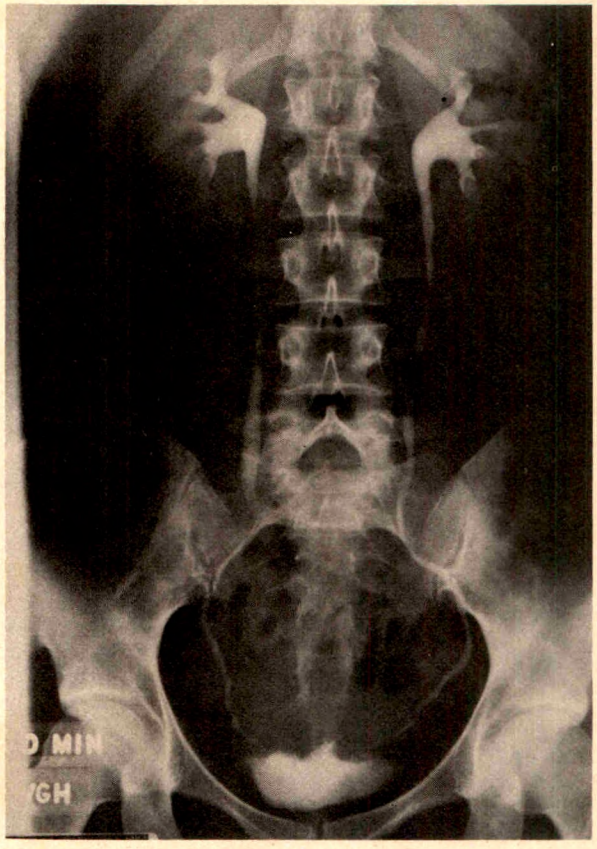

Fig. 6. Intravenous urography at 10 minutes in Case No. 6, showing involvement of the bladder wall with ureteral dilatation above pelvic brim.

outside the cul-de-sac (Fig. 9). Continued observation disclosed a gradually enlarging 4 cm mass in the right uterosacral ligament, which was confirmed by sonography, and intravenous urography showed medial displacement and angulation of the distal ureter with partially obstructed drainage (Fig. 10, *A*). At exploration a 3 by 4 cm endometrioma was found in the right uterosacral ligament and, because of the fairly restricted extent of the disease and a strong desire for children, the procedure was restricted to resection of endometriosis, ureteral lysis, and appendectomy. In such cases careful surveillance is mandatory to ensure continued renal integrity.

In all, three (or possibly four since in Case No. 6 there was a single but extensive endometrioma) of these eight patients had restricted foci of endometriosis primarily involving the uterosacral ligament and/or cardinal ligaments. In three of these instances, despite the threat of future renal problems, the patient was not castrated and the possibility of childbearing was maintained.

Comment

Endometriosis involving the urinary tract is not a completely benign condition. This series and others[2, 10] indicate that 25% of kidneys are lost when endometriosis obstructs the ureter. Ureteral obstruction may occur with extensive pelvic endometriosis but is most likely to occur with minimal extent of the disease when the uterosacral ligaments are involved. The experience reported here shows three cases of ureteral obstruction, including the loss of a kidney, with endometriosis which was virtually restricted to the uterosacral ligaments. Careful appraisal of the uterosacral ligaments and urologic evaluation at least by intravenous urography should be carried out if endometriosis is to be managed expectantly.

Most instances of ureteral obstruction occur insidiously with less than half of the patients showing symptoms of upper urinary tract dysfunction. Headache, backache, and hypertension point to the likelihood of upper urinary tract obstruction. Pyelonephritis is seldom associated with endometriotic obstruction and renal death may be relatively silent. Too often, as in

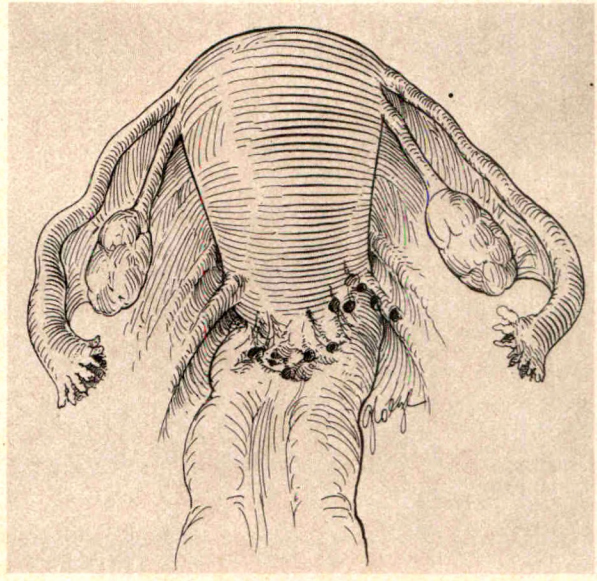

Fig. 9. Minimal endometriosis involving the cul-de-sac and right uterosacral ligament proved by translaparoscopic biopsy 3 years prior to ureteral lysis for angulation, fixation, and deviation of right ureter by endometrioma.

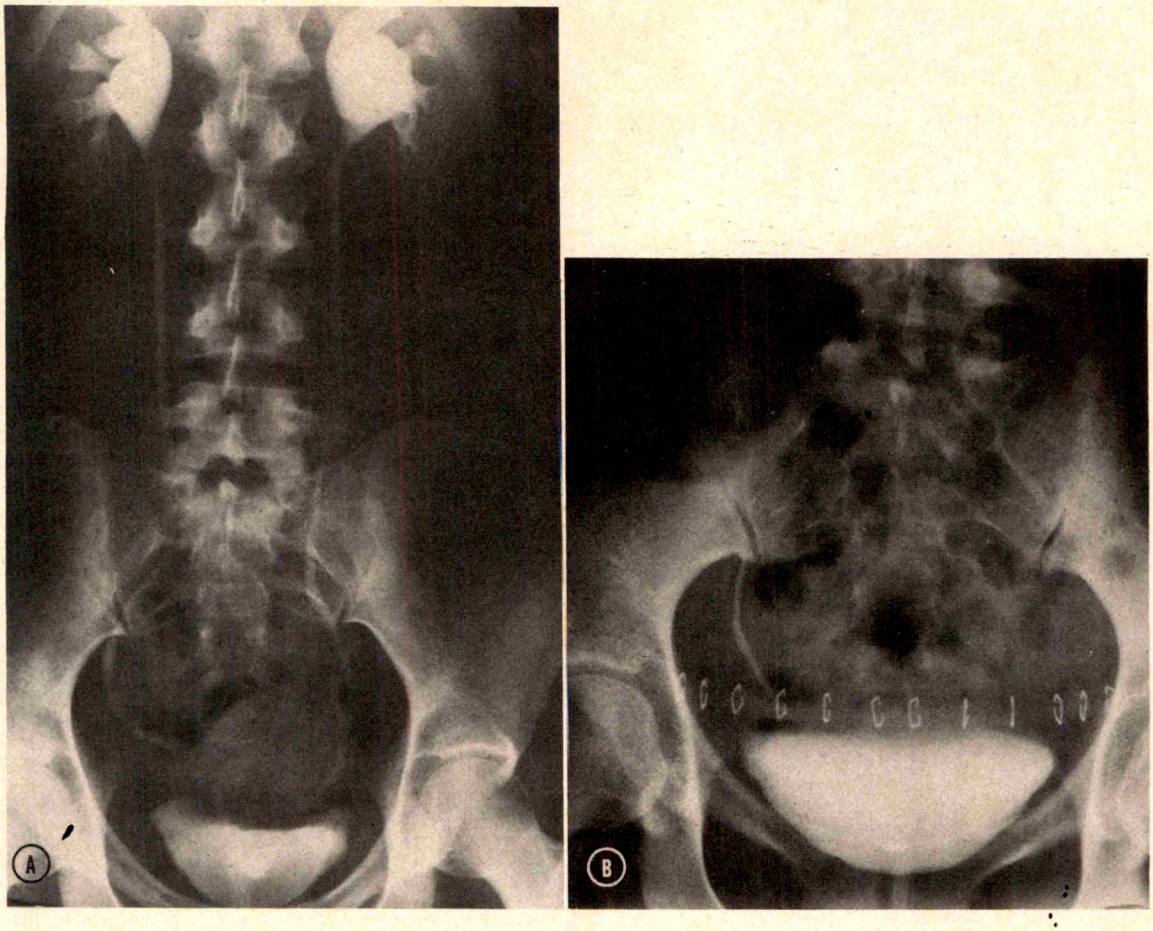

Fig. 10. Intravenous urography at 12 minutes *(A)* in Case No. 8, showing deviation and obstructed drainage of the right ureter and normal course of right ureter following operation *(B)*.

Cases 4 and 5, renal cortical destruction is suggested by hypertension and headaches and confirmed by greatly delayed or absent kidney function on intravenous urography with renal arteriography demonstrating a minimal renal cortex. Subsidence of hypertension and reduction of proximal ureteral distention is not necessarily a sign of improvement and may, as in Case No. 5, indicate fairly complete renal cortical destruction. Ureteral implantation in such instances has a poor chance of success.

Following a reasonable parity and especially if the patient is over 35 years of age, endometriosis should be treated aggressively. This tenet is especially true if there is urinary tract involvement. Under these circumstances, as others have wisely proclaimed,[2, 3] there is no place for conservationistic management, as was well illustrated in Case No. 7. Less than resection of the endometriomas, relief of urinary tract obstruction, and ovarian ablation does not represent conservative or prudent management. It represents an invitation to further difficulties and imposes a 25% chance for the loss of a kidney. If, in the interests of continued reproductive capability, the endometriosis is resected and the ureteral obstruction is relieved but ovarian function is maintained, then periodic surveillance of urinary integrity is well advised.

Discussion

DR. CHARLES F. LANGMADE, Pasadena, California. Nothing is absolute, nothing is 100%, and Dr. Moore has pointed out to us that total removal of all ovarian tissue, hysterectomy, and lysis of ureteral obstruction is not always the best form of management as we suggested in 1974. When child-bearing must be preserved, the ideal method of management must be compromised and this part of the paper is a real contribution.

Surely in the young 21-year-old nulliparous patient, Case No. 8 in the series, attention must be given to her desires and her wishes for having a family. On the other hand, the 44-year-old woman, para 2, gravida 3, with a long history of endometriosis and sterility should be treated quite differently. Surgical exploration in Case 7 revealed extensive disease requiring resection of the bladder, rectosigmoid bowel, and an endometrioma of the ovary. I would like to ask Dr. Moore how it was decided to resect the endometrioma rather than remove all the ovarian tissue. The patient had already undergone hysterectomy. She may have been adamant in regard to definitive complete surgery; however, ideally she should have had all ovarian tissue removed and retroperitoneal exploration to be sure that this was accomplished.

In Cases 1, 2, 3, and 4, all the ovaries were removed and to this we agree. In Case No. 5, a 33-year-old woman gravida 4, para 1, therapeutic abortions 3, with hypertension had symptoms of endometriosis for 4 years. At operation, she required resection of the left kidney, ureter, and rectosigmoid bowel and, in general, had extensive disease. We must ask ourselves again what the chances are for this patient to conceive. At operation, the patient of Case No. 6 required resection of the bladder, omentum, and transverse colon and ureteral lysis and her possible child-bearing function was preserved.

We agree with Dr. Moore's management of Cases 1, 2, 3, 4, and 8. Cases 5, 6, and 7, in our opinion, should have had complete removal of all ovarian tissue. I would like to ask Dr. Moore if these three patients were strongly advised to have complete surgery for their disease. If they were and refused then we understand the management. We now have seven cases of ureteral obstruction due to endometriosis and in no instance was definitive surgery refused.

There are only a few controversial points put forth in the paper. The term "castration" should be abandoned. Somehow this eventually gets through to the patient and then sets a very different stage than the careful explanation that removal of all ovarian tissue should be done and the endocrine secretion can safely be supplied by oral estrogens. Dr. Moore rightly uses oral estrogens following definitive surgery for endometriosis. It has been suggested that estrogens will stimulate the remaining endometrial tissue, which is not true if

both ovaries have been removed. It remains questionable if Norlutate "suppresses" endometrial tissue after ovarian removal. Laparoscopic examination in a patient with palpable disease and an obstructed ureter is probably not indicated unless for teaching purposes. In many instances and in Dr. Moore's report, the disease is almost a retroperitoneal desmoid reaction and will not be seen on laparoscopy.

Entering a partially obstructed ureter with a nonfunctioning or hydronephrotic kidney will lead to severe infection in some instances and simple lysis of the obstruction would seem preferable. Dr. Moore encountered no such problem in his cases requiring ureteral resection. Presacral neurectomy is of questionable value in extensive adnexal disease.

The diagnosis of endometriosis continues to be missed, but it would seem preferable to have the history and minimal pelvic findings lead us to ordering an intravenous pyelogram rather than the intravenous pyelogram leading us to the diagnosis. Symptoms, however, may be very sparse. In one case reported in 1974, endometriosis extended through the vagina and bladder to both side walls and destroyed one kidney, yet she had not one day of pain. We should order more intravenous pyelograms in patients with endometriosis.

The postoperative intravenous pyelogram in Case No. 8 appears little changed from the preoperative one. The dye is still retained on the involved side and the course seems about the same. I would like to ask Dr. Moore if subsequent studies showed this to be completely resolved.

It is heartening to hear such a paper coming from three large institutions; University of California, Los Angeles, Cedars of Sinai and Los Angeles County–University of Southern California. Endometriosis imposes sterility on a great number of real achievers in our country today. I am unaware of any large-scale, long-term research program to eradicate the disease. Dr. Moore and his co-authors are in positions to do this and I sincerely hope further studies will be done.

DR. EDWARD C. HILL, San Francisco, California. It has been my impression that in most instances in which the ureter is obstructed by an endometriotic process, it does so by compression, rather than by actual involvement of the ureteral wall. This was borne out in the microscopic section of the ureter that Dr. Moore presented. I would ask Dr. Moore whether in his experience, in any of these cases, particularly those in which there was a ureteroneocystostomy, there was actual involvement of the ureteral wall itself.

DR. ERNEST A. WATERMAN, Portland, Oregon. A fascinating series of patients with endometriosis was presented. None of these apparently had a history of previous use of an intrauterine contraceptive device. If it is valid that retrograde menstration is a possible etiologic factor in the development of endometriosis, and since one of the optimal times for intrauterine contraceptive device insertion is during the menses, does Dr. Moore feel that we may anticipate, in the near future, an increase in the incidence of endometriosis in our practices?

DR. CHARLES WEBER, La Jolla, California. I would like to ask Dr. Moore whether or not he actually had anticipated urinary tract involvement in any of the cases reported, and if so how many?

DR. EDWIN T. MACCAMY, Seattle, Washington. Dr. Moore, what is dyschezia? Do you always anticipate having to enter the bowel; if so, how do you prepare the bowel?

DR. GILBERT A. WEBB, San Francisco, California. During my residency, I had the pleasure of assisting Dr. Trout—late of this Society—on a case of pelvic endometriosis where the left ureter was involved. What makes this case unique was that the patient had had a left nephrectomy in the previous year because of persistent hematuria. This had been studied by the urologist and indentified as coming from the left ureteral orifice. An assumption was made of a small obscure cancer of the left kidney as the intravenous pyelogram and retrograde studies were normal. Histologic studies of the removed specimen failed to reveal any malignancy. Thus the accurate diagnosis was not established until laparotomy revealed ureteral involvement by the endometriosis. Thus complaint of hematuria in the female patient may be the first indication of urinary tract involvement of endometriosis.

DR. ENRIQUE C. M. DECASTRO, Portland, Oregon. Dr. Moore says "curiously the ovary was not involved" in one of his cases of endometriosis involving the uterosacral ligaments. It has been our observation that many times we do find that when the uterosacral ligaments are involved early in the course of the disease the ovaries are free of disease. I wonder in these situations whether one would consider conserving the ovary. I do feel that there are different etiologies in endometriosis. In those cases involving the uterosacral ligaments (retrograde menstruation theory) many times we will find the ovaries completely free of disease. In the past, we have all felt that complete removal of the ovaries is a necessity, but I am beginning to wonder if there are not instances where this could be avoided.

DR. MOORE (Closing). Dr. Langmade, I agree that the preferred management of patients with endometriotic obstruction or compression of the ureters is to ablate the ovaries, to remove the uterus, and to maintain the patient on a regimen of oral estrogens. I am not sure, in my own mind, how persuasive we should be in encouraging young, nulliparous patients to have surgical ablation of the ovaries. I think somewhat as Dr. deCastro alluded to, that perhaps if you encourage better egress of the menstrual flow, if you resect all evidence of the endometriosis, and if you watch the patients carefully, they may have a few years at least to have their children. During that time, with careful surveillance, I am not sure that there is a great risk to the kidneys—although there is a risk to subsequent sur-

gery. I think these factors have to be discussed with the patient, and I feel strongly that we should not be excessively persuasive, perhaps excessively is not exactly the term, in guiding their treatment. I think they have to make that decision with a full knowledge of the risks. Dr. Langmade is right that there were two patients who were followed up for a considerable period of time when the ovaries and uterus should have been removed previously. They were observed elsewhere. One in the Phillipines (Case No. 7), who really had a horrendous history, as I think you noted, had a bowel obstruction. She later had the uterus and what was thought to be all ovarian tissue removed, but indeed the right ovary had not been completely removed and we found a corpus luteum in it at the time of resecting the persisting endometrioma for ureteral obstruction. Dr. Langmade referred to Case No. 8 and indicated that the right ureter did not seem to be too different postoperatively than it was preoperatively. You did not see it stated on the film in the slides, but it was taken 4 days postoperatively and I think there was still some edema in the field. We have since obtained a subsequent intravenous pyelogram and she has perfect drainage.

Dr. Hill, the instances of intrinsic involvement of the ureter, rather than oppression, in which the ureters were completely obstructed by the endometriosis occurred in Cases 4 and 5. Both of those lesions involved the base of the cardinal ligaments and the uterosacral ligaments and they had to be approached in the same way a radical hysterectomy is approached by entering the areas below and above the web and transecting the cardinal ligament right at the pelvic wall.

Dr. Waterman, I do not know if we can anticipate an increase in the amount of endometriosis in patients who have intrauterine contraceptive devices in place. Perhaps the device does interfere with the proper flow of menses and increase reflux, but for me it would be complete speculation and I have no evidence.

Dr. Weber, we anticipated urinary tract involvement in only four of the patients before we obtained the urinary tract studies. Then of course it became fairly obvious. In none of these instances was it a complete surprise at operation.

Dr. MacCamy, "dyschezia" means "painful defecation." It generally is associated with uterosacral ligament or cul-de-sac involvement. We did not, in any of these cases, anticipate entering the bowel. Had we so anticipated, I suppose that we would have prepared the bowel with neomycin.

Dr. deCastro, I think your point was most thoughtful. When the uterosacral ligaments are involved and not the ovaries or the peritoneal surfaces at the pelvic brim, it probably means that there has been the drippage, if you will, of menstrual reflux onto the uterosacral ligaments; at least that seems somewhat logical. I would say that when the ovaries are free of disease and the uterosacral ligaments alone are involved, perhaps we should look toward a better path of egress for the menstrual flow. As a matter of fact, Dr. Schifrin and I published an article on teenage endometriosis some 10 years ago in which this was the major thesis. In a young woman who has excruciating and incapacitating dysmenorrhea, we should look for some obstruction to menstrual flow, such as a blind uterine horn. Carrying that a little bit further, perhaps a wide dilatation of the cervix might be in order. In these young patients, who might be prone to dysmenorrhea and who demonstrate endometriosis on the uterosacral ligaments at laparoscopy, perhaps the cervix should be widely dilated. At least, one should look for a septum in the uterus that might be a cause of partial obstruction of flow. I should like to thank Dr. deCastro for bringing up that important point.

Maternal deaths associated with postpartum vulvar edema

THOMAS L. EWING, M.D.
LEROY E. SMALE, M.D.
FRANK A. ELLIOTT, M.D.
Bakersfield and Los Angeles, California

Reported are three maternal deaths in four patients who presented with a similar syndrome following a normal antepartum course and normal labor and delivery managed by regional or local anesthesia and midline or proctoepisiotomy. Beginning about the second postpartum day, the patients developed unilateral perineal edema and induration which progressed to generalized vulvar, vaginal, perineal, and gluteal edema and induration. These patients developed marked leukocytosis, fever, and ultimately vascular collapse; three of them died. The one patient who survived had a similar course except for vascular collapse. Unilateral vulvar induration and edema associated with fever and marked leukocytosis are ominous signs. Aggressive treatment should include the use of multiple antibiotic, crystaloid, colloid, and steroid drugs and appropriate monitoring. By this report we hope to bring attention to this rare but lethal syndrome. (AM. J. OBSTET. GYNECOL. 134:173, 1979.)

THIS REPORT concerns itself with the description of a syndrome resulting in three maternal deaths and one survival in which all patients had normal antenatal and intrapartum courses. Two or three days later the patients developed a progressive illness characterized first by the development of unilateral vulvar and perineal edema and induration. This extended next to the contralateral side and to the inner pelvis. All patients developed fever and marked leukocytosis. Ultimately all but one patient developed vascular collapse and died. Because of the striking similarity of the manifestations in each of the patients and the scarcity of reports concerning this syndrome, a report describing the findings in these patients seems warranted.

Material and results

During the period (1969 to 1976 inclusive) these patients were observed and treated, eight additional maternal deaths in 49,007 live births occurred in the County of Kern, California. Table I lists the causes of these deaths in addition to two of the three deaths comprising this report.

Table I. Maternal deaths: Kern County (1969 to 1976)*

Year	*No. of deaths*	*Cause*	*Rate/ 10,000 live births*	*No. of births in Kern County*
1969	2	Sepsis†	3.3	6,107
1970	3	Pulmonary embolism	4.7	6,339
1971	1	Angioneurotic edema†	1.6	6,147
1972	0	–	–	6,005
1973	3	Eclampsia (dead on arrival), infectious hepatitis, and pulmonary embolism	5.6	5,388
1974	0	–	–	6,109
1975	2	Fatty metamorphosis of liver, accidental death	3.1	6,374
1976	0	–	–	6,538
Total	10			49,007

*One of our patients died in Los Angeles County Hospital.
†Reported in this paper.

Table II summarizes the clinical data of the four patients comprising this report. It should be noted that

Case No.	*Hospital Identification No.*	*Age (yr.)*	*Parity*	*Duration of pregnancy*	*Delivery*	*Anesthesia*	*Type of episiotomy*	*Onset of vulvar edema*	*White blood cell count (No./cu mm)*	*Onset of vascular collapse*
1	443554-1969	19	1	Term	Low forceps	Caudal plus saddle-block	Procto-episiotomy	Second postpartum day	33,000, 57,000, left shift	Fourth postpartum day
2	467908-1971	16	1	Term	Low forceps	Epidural	Midline with third-degree extension	Second postpartum day	32,500, left shift	Fourth postpartum day
3	395442-1976	24	2	Term	Spontaneous delivery	Pudendal	Midline	Third postpartum day	30,200, left shift	Fourth postpartum day
4	356516-1976	15	1	Term	Low forceps	Saddle-block	Procto-episiotomy	Third postpartum day	22,300, 27,000, left shift	None

Case No. 3 was also included in the report by Golde and Ledger.[2]

Comment

Although the microbial agents responsible for this syndrome in these women have not been identified, the clinical course represents a form of bacterial gangrene as described by Borkowf.[1] He identified two clinical courses: (1) a gas gangrene caused by *Clostridia* or a necrotizing fasciitis classically caused by anaerobic streptococcus, and (2) a less virulent form of progressive synergistic bacterial gangrene classically caused by streptococcus and pathogenic staphylococcus in combination. These are old terms and antedate the antibiotic era. Rea and Wyrick,[5] writing on necrotizing fasciitis, stated that the most significant manifestation of this infection is "extensive necrosis of the superficial fascia which results in widespread undermining of the surrounding tissue and extreme systemic toxicity regarding less of the specific bacterial etiology." The initiating injury leading to these infections was minor trauma in 80% of their cases. In many cases the trauma was located on the abdomen or extremities. None occurred in the perineal areas. Their treatment consisted of antibiotics and wide surgical debridement. Antibiotics alone did not appear to lower the mortality rate. Their mortality rate was 30% and this was mostly in those patients who had diabetes or arteriosclerosis. The average time from the onset of the disease to the initiation of therapy was 4 days among the survivors. Prominent features of each of the bacterial gangrenes are skin manifestations, usually some evidence of necrosis and often a foul "fish-water" discharge. Stone and Martin[6] described a synergistic necrotizing cellulitis. Some cases started in the perineum. These patients were almost entirely diabetic and debilitated and beyond 50 years of age. They reported a high mortality rate from these lesions because of inaccessibility and inability to debride.

Our cases are characterized by massive edema (Fig. 1) and compromised blood supply as evidence by the paucity of bleeding from cut surfaces. With the exception of the patient sent to the University of Southern California Medical Center, skin necrosis was not evident and a foul-smelling "fish-water" discharge was not present. The common histologic change found in all biopsy and autopsy sections is one of subcutaneous and soft tissue edema and inflammation beginning unilaterally in the area of the episiotomies. Edema was present not only in the vulvar tissues but also at autopsy in

X-ray and ultrasound examinations	*Fever ℃*	*Operative intervention*	*Cultures*	*Treatment*	*Outcome and comment*
Pleural effusion, obliteration of psoas shadows	39.4°	Incision and drainage of ischiorectal fossa. No abscess found. Minimal bleeding	None	Ampicillin, kanamycin, corticosteroids, chloramphenicol, crystalloids, colloids and heparin	Died sixth postpartum day. Autopsy denied
–	38.5°	Tracheotomy	Urine and blood cultures—negative. Lochia—klebsiella, aerobacter, bacteroides	Local heat, Carbenicillin, kanamycin, gentamicin, cortisone, crystalloids	Died fourth postpartum day. Autopsy findings, limited to perineal vaginal tissues, showed marked hemorrhage, inflammation, and edema
–	38.2°	1. Episiotomy opened and incision and drainage of vagina and gluteal areas. No bleeding. 2. Colostomy. Debridement of perineum. Subtotal hysterectomy	Perineum and vaginal tissues—streptococci, *Clostridium sordellii*, staphylococci (coagulase negative)	Cephalothin, chloramphenicol, gentamicin, corticosteroids, crystalloids	Died on fourth postpartum day. Histology showed subepithelial necrosis, inflammation, and necrosis of perineum
Intravenous pyelogram, sonography showed right-sided pelvic mass	37.2°	Episiotomy opened. No bleeding	Urine and blood—all negative	Penicillin, gentamicin, ampicillin, corticosteroids, crystalloids, colloids	Alive. Discharged on twenty-third postpartum day

the retroperitoneal tissues and the mesentery.

No definite etiology has been determined nor has any commonalty in medications, type of suture materials, or infectious agents emerged. Special histologic examinations for both bacteria and fungi were negative. Search for possible sources of contamination in the patients comprising this report has been nonproductive. No reports of infections from contaminated suture material have appeared in the past 10 years (Med-Line search), although many decades ago catgut clostridial infections sometimes arose from viable spores remaining in the raw materials. Such infections would have identifiable epidemiologic characteristics. A possible source of infection is the patient herself. Since each of these patients had a midline episiotomy or an extension into the anal and/or rectal area by deliberate incision (proctoepisiotomy) or spontaneously, contamination from the fecal stream is a possibility and also from anaerobic microbial organisms normally present in the vagina. Except for Case No. 3 no positive blood or tissue cultures were obtained in any of the patients. The positive cultures from the lochia have no probable significance since similar organisms can be grown from asymptomatic postpartum patients. Also organisms isolated in Case No. 3 (*Clostridium sordellii* and coagulase-negative staphylococcus) probably are not the pathogens causing the patients' state.[4]

Our patients were all healthy pregnant women with no known complicating disease. Hibbard and associates[3] reported unusual postpartum infections in women who had normal antenatal courses and normal labor and deliveries. Six of them had either subgluteal or retropsoas abscesses. These infections followed paracervical or pudendal blocks and often required surgical drainage and debridement. Likewise our patients had normal pregnancies, labors, and deliveries; the "infections" began in the episiotomies and were not purulent but were characterized by massive edema and induration of the vulvar, gluteal, and perineal areas and extended to one or both pelvic side walls (Figs. 1 to 3, Case No. 4). Ultimately intravascular volume could not be maintained and the patients died.

Golde and Ledger[2] reported three postpartum patients with vulvar edema and one patient who had a necrotizing fasciitis in an incision for cesarean section. One of their patients (Case No. 3) had features similar to those of the cases reported here. Only one of their unique patients (Case No. 1) presented with features similar to those of our cases: vaginal delivery, fourth-

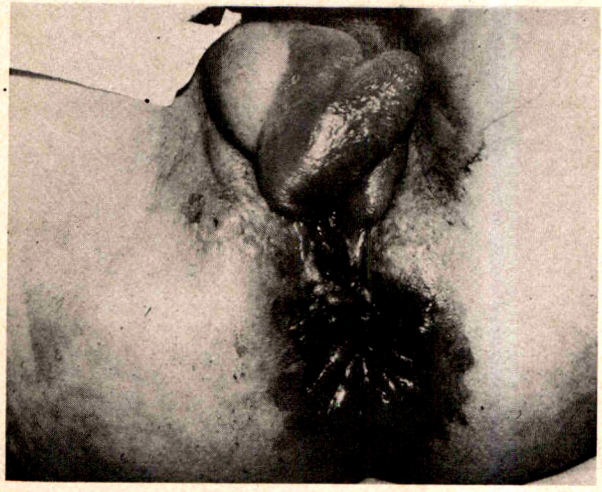

Fig. 1. Unilateral labial edema on fourth postpartum day (Case No. 4).

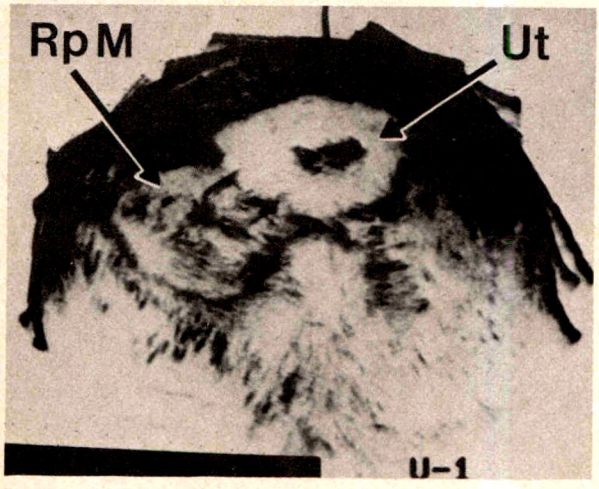

Fig. 2. Ultrasonogram showing unilateral abdominal mass *(RpM)* (Case No. 4).

degree perineal extension, and the subsequent development of a similar clinical course. Their other unique patient differed from our patients' courses in that she developed multiple abscesses of the perivaginal and retroperitoneal tissues.

From our experience we recommend early assessment of vulvar edema, particularly when it is asymmetric and occurs approximately within 48 hours after delivery. Asymmetry makes the edema distinguishable from more common causes of vulvar edema secondary to prolonged labor, etc. Temperature elevations are often of a low grade and the patient initially is reasonably asymptomatic aside from vulvar pain. The white blood cell count will most likely be greater than 20,000/cu mm with a left shift. Once the diagnosis is suspected we recommend high doses of penicillin, gentamicin, chloramphenicol, and steroids. A central venous catheter should be placed at the first sign of intravascular volume depletion and perhaps intraarterial and pulmonary wedge pressures should be monitored to guide crystalloid and colloid therapy. The anatomic location of this disease and its rapid spread up the pelvic side wall makes pelvic perineal debridement difficult and unsatisfactory. Our one surviving patient did not have tissue necrosis but cellulitis which responded slowly to the antibiotic drugs given.

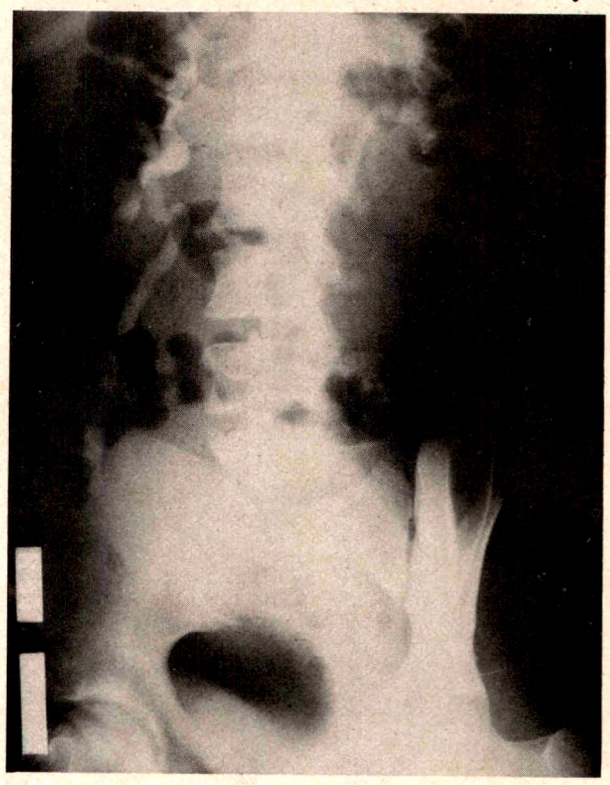

Fig. 3. Intravenous pyelogram showing deviation of ureter by mass shown in Fig. 3 (Case No. 4).

We believe this report to be pertinent because early recognition seems critical for prevention of maternal death. Aside from the report in 1977, by Golde and Ledger,[2] we have been unable to find any reports concerning vulvar edema secondary to episiotomy infection. Since only one of our patients survived, we believe also that histologic and bacteriologic study of subsequent surviving patients may shed information about an inherent idiosyncratic or immunologic deficiency that may contribute to this fatal disease.

We wish to thank Dr. Elizabeth Admiral for use of her case (Case No. 3) and Roger Terry, M.D., surgical pathologist, Los Angeles County–University of Southern California Medical Center, for his review of the tissue sections in Case No. 3.

Discussion

DR. WILLIAM C. SCOTT, Tucson, Arizona. Acute vulvar edema is not strange to the gynecologist, occurring not uncommonly in association with trauma, infection, primary irritant dermatitis, allergic contact dermatitis, and Crohn's disease and has even been reported following paracentesis. In the vast majority of instances, however, its appearance is far from indicating a life-threatening situation. The acute hemolytic streptococcus gangrene described by Meleney,[1] in 1929, started from a superficial break in the skin and spread rapidly and alarmingly over the next 24 to 72 hours with profound prostration. The area became red, swollen, and painful with a poorly demarcated margin fading off gradually into relatively normal skin. If the process went on long enough the pathognomonic signs of dusky hew and blistering in patches developed, ending ultimately in frank gangrene. It was his belief that the rapidity and the profundity of the clinical infection suggested that the disease might be due to the entrance of organisms into the body at a time when it was in a hypersensitive state.

Following Meleney's original work the surgical literature was replete with articles describing similar syndromes later named "necrotizing fasciitis"[2] and from which a variety of organisms in addition to the hemolytic streptococcus were cultured. In addition, a necrotizing lesion of a more indolent course called "progressive bacterial synergistic gangrene" was identified.[3] Subsequent authors have reported postsurgical cases of progressive gangrene resistant to antibiotic therapy, for which they prescribed wide surgical excision, and a confusion has existed between these two diagnoses, with more recent authors feeling that they represent different facets of the same disease.[4] The first involvement of gynecology in the case reports was that of Sandusky and associates,[5] in 1942,[5] who reported 170 cases of anaerobic nonhemolytic streptococcal infection including three Bartholin's gland abscesses and one case of postsurgical salpingitis. Thirty years later Roberts and Hester[6] reported necrotizing fasciitis in six vulvar and Bartholin abscess cases. Keettel, in his discussion of their paper reported an additional Bartholin's gland abscess and two post–cesarean section cases of uterine necrosis with abdominal gangrene. Hibbard and associates,[7] in 1972, brought to our attention eight patients having uncomplicated labor and delivery, all of whom had either pericervical or pudendal block and who developed fascial and vulvar infection. One of their patients developed the typical labial edema, cellulitis, and course of necrotizing fasciitis but survived with antibiotic therapy. Bahary and associates,[4] in 1977, and Daly and associates,[8] in 1978, reported gynecologic infections with a similar course. Golde and Ledger[9] reported four cases, one of which is included in the present report, and now the present authors have added three additional cases to bring attention to this extremely serious postpartum pelvic infection with its fulminating course and high mortality rate.

Golde and Ledger, in reporting their four cases occurring during a period when there were 109,531 deliveries at Los Angeles County–University of Southern California Medical Center, emphasized by their figures the fact that this was indeed a rare condition. I would like to add to this present series a case of my own as well as to report one from Denver because I believe that despite the paucity of reports in the literature the condition is one about which every obstetrician should be concerned. To be immediately alarmed by the presence of postpartum labial edema, especially unilateral, is to be forewarned of the necessity to promptly begin antibiotic therapy with high doses of intravenous penicillin and intramuscular gentamicin and Cleocin.

A 23-year-old woman, gravida 1, para 0, with RH-positive, Type O blood, following a normal, uncomplicated pregnancy, was admitted at term with membranes intact and was delivered of a 6 pound, 5 ounce infant by spontaneous vaginal delivery following episiotomy and pudendal block on July 1, 1970. Twelve hours post partum the patient had a temperature of 99.2° F and pale vulvar edema which at that time was thought to be due to allergy to pHisoHex. The white count was 21,800/cu mm. On the second post partum day the vulvar edema was unchanged, the temperature and pulse were normal, and she was discharged. Twelve hours later she was readmitted with acute vulvar pain. On the third postpartum day the temperature was normal and the edema had spread to involve the lower abdomen and upper thigh. On the morning of the fourth postpartum day the patient had a purulent vaginal discharge from which clostridia was later cultured. Suddenly at 1200 on the fourth postpartum day the patient went into endotoxic shock. Intravenous antibiotic drugs and Solu-Cortef were started and with increasing amounts of intravenous fluids the urinary output was maintained. Despite medical management the patient went into irreversible shock and died on the fifth postpartum day. Autopsy findings revealed extreme brawny vulvar and lower abdominal edema with some degree of redness and poorly defined margins. There was retroperitoneal edema with massive amounts of fluid as well as free fluid within the abdominal and thoracic cavities. The tissue in the area of the episiotomy and ischiorectal fascia showed necrosis. The blood culture was negative and culture of tissues at autopsy was negative.

In retrospect, the prompt and early administration of large doses of antibiotic drugs at the onset of the

disease on the first postpartum day might well have prevented the ultimate death of the patient. It certainly underscores Keettel's warning, "The postpartum patient who becomes febrile and has hip or buttock pain should be suspect." An almost identical case has been reported by personal communication from Dr. Watson Bowes, occurring in St. Joseph's Hospital, Denver, Colorado. The death certificate stated "acute angioneurotic edema."

I wish to compliment the authors for bringing to our attention and through the literature to the attention of all obstetricians a rare but extremely serious complication of pregnancy. As they suggest, only prompt recognition and intensive antibiotic therapy seem at the present time to provide the decreasing mortality rates.

Drs. Ewing, Smale, and Elliott have recommended in addition high doses of steroids as soon as the diagnosis is established. As steroids have accepted value only in the presence of ligneous cellulitis and endotoxic shock and presumably could interfere with leukocytic response to this overwhelming mixed infection, I seriously question their usage in the initial phases of treatment. In their cases as well as mine antibiotic therapy was too little and too late.

Five of the six cases reviewed here were in primiparous patients, thus setting the stage for trauma in an area potentially colonized by clostridia and streptococci as well as anaerobic organisms. In the authors' cases were x-ray films obtained for gas in the pelvic tissues? Were hematomas present? And since they suggest an immunologic deficiency, what were their patients' histories of resistance to prior infection? Finally why is this complication so rare?

Dr. Lester T. Hibbard, Los Angeles, California. I would like to add two cases to Dr. Smale's collection, both taken from the Maternal Mortality Study in California.

A 30-year-old woman, para 1, was delivered uneventfully except for a fourth-degree extension of a midline episiotomy. Thirty-six hours later, brawny edema was noted in the left labia majora and spread rapidly down both legs and up into the abdominal wall. A large loss of plasma into subcutaneous tissues was suspected on the basis of a 20 point rise in hematocrit. During the next 10 days, edema spread to involve the entire body, despite the use of steroids and muliple antibiotic drugs. Debridement was considered but rejected because of the extensiveness of the process. All cultures were negative and there was no crepitus or abscess formation. Subsequently the patient died. The autopsy diagnosis was toxic cellulitis of uncertain origin.

A 19-year-old woman, para 0, was delivered uneventfully with the aid of a left mediolateral episiotomy. On the second postoperative day, a swelling of the left labia and left buttock was noted along with chills and fever of 101° F. Triple-antibiotic therapy was begun, but the swelling increased dramatically and the patient lapsed into shock with evidence of a massive loss of plasma. The episiotomy was reopened to reveal nothing more than cellulitis from which *E. coli,* nonhemolytic streptococci, and *Clostridium perfringens* were recovered. However, there was no clinical evidence of a clostridial infection. Two treatments in a hyperbaric chamber brought temporary improvement, but the patient died before a third treatment could be started. An autopsy was inconclusive except for the demonstration of cellulitis.

Both of these patients had the benefit of multiple consultations and discussion.

Dr. John J. Molitor, Fullerton, California. The majority of patients in this series had midline episiotomies with extensions into the rectum. Most of the residents today disdain the mediolateral episiotomy and prefer the midline incision. I still think there is a place for the mediolateral incision and I use it if I think the rectum is going to be entered, because it lessens the contamination of the perineum. I have noted no difference in postoperative pain or swelling with the use of polyglycolic sutures.

Dr. Smale mentioned the elevated white blood cell counts. Several years ago, one of my colleagues was sued by a patient who developed sepsis several days after she went home following delivery. Many of our patients now go home in 24 hours. During the last 2 years, we have obtained complete blood counts on the patients the first postpartum day. We have been amazed to see that white blood cell counts of 20,000/cu mm are common. Counts of twenty-three and 23,000/cu mm and 24,000/cu mm with a marked shift to the left are frequent. So, I do not think that the white blood cell count particularly helps in the diagnosis. On the other hand, if these patients, on the first or second postpartum day, have an elevated white blood cell count it does not necessarily mean that they have infec-

tion, because most all of these patients I mentioned had no postpartum difficulties after they went home.

In my experience, unilateral edema of the vulva following delivery is usually due to hematoma in the pelvis. Frequently this has occurred where the fetal head came into close approximation with the ischial spine and a vessel was ruptured submucosally. A hematoma develops and the patients experience a great deal of pain and swelling. When the hematoma is evacuated the symptoms are relieved and the patients recover.

DR. KEITH P. RUSSELL, Los Angeles, California. I believe that not enough attention has been paid to another factor which may enter into this condition, and that is the use of local anesthesia injected in the area. We often take too much for granted that the injection of medication for pudendal or perineal block is without hazard. Some of these cases correlate with the type of reaction seen with local anesthesia or a contaminated injectable agent. It reminds me of the problem a number of years ago of infections after spinal anesthesia, which was being used frequently. A number of these cases were traced to cracks in the drug containers, with contamination of the material which was injected. I think that until this factor is at least considered we must look to this possible etiology and not assume that this is some rare clinical occurrence. We must review the material that is being injected into these tissues, which then may become severely edematous and/or infected.

DR. ROBERT H. GREGG, Covina, California. In the evolution of this most serious problem, I am interested in knowing the status of the vascular tree, both venous and arterial, as well as the status of the hemodynamics and intravascular clotting mechanism.

DR. SMALE (Closing). In most of our patients we started steroids after the patient began to lose intravascular volume, which was early in the course of the disease. We felt that these patients were developing disseminated intravascular coagulation and we were using the steroids as one of the things to hopefully "plug up" the holes in the vessels. We did obtain x-ray pictures and there was no visualized gas, and there were no hematomas. We certainly considered hematoma as one of the first things for which to search.

These were all young ladies and all were in good health. We have no idea why it is so rare, but we are glad it is such a rare disease because it is really a very lethal one in our experience. I appreciate Dr. Hibbard's contribution of the two additional case reports and his attitude, because the more information in the literature, the more important it is going to become to all of us as obstetricians and gynecologists. As far as anesthesia is concerned, only one of the four patients had any local anesthesia; the rest had epidural or saddle-block anesthesia and one received a caudal anesthetic drug.

A study of endocrine and metabolic variables in postmenopausal women with endometrial carcinoma

WILLIAM E. LUCAS, M.D.
SAMUEL S. C. YEN, M.D.
San Diego, California

Although an underlying endocrine-metabolic disorder has been implicated as causally related to the development of endometrial carcinoma, data to support such an association are ambiguous and/or contradictory. In this prospective study of 16 consecutive nonobese postmenopausal women with endometrial carcinoma and 16 cancer-free postmenopausal women matched for age and weight, fasting values for growth hormone (GH), insulin, prolactin, follicle-stimulating hormone, luteinizing hormone, estrone (E_1), and estradiol (E_2) were measured on 3 consecutive days. Intravenous glucose tolerance, pituitary GH release in response to arginine infusion, hyperglycemia, and hypoglycemia, and insulin secretion in response to arginine infusion and to hyperglycemia were analyzed. Our data show that these endocrine-metabolic profiles were not significantly different between the cancer patients and control subjects, suggesting that the postmenopausal woman with endometrial cancer who is not obese exhibits no accountable endocrine or metabolic disorders.
(AM. J. OBSTET. GYNECOL. 134:180, 1979.)

A DOGMA IN GYNECOLOGY is the concept that endometrial adenocarcinoma is often associated with an endocrine-metabolic disorder manifested by obesity, infertility, and impaired carbohydrate tolerance. There is considerable epidemiologic evidence that obesity and infertility are risk factors in the development of endometrial cancer.[1, 2] However, there are no consistent data which support specific and reproducible abnormalities of hypothalamic, anterior pituitary, or ovarian function. Moreover the frequently cited higher incidence of diabetes in association with endometrial carcinoma remains controversial.[3, 4]

Benjamin and associates[5, 6] have observed that both hyperglycemia after oral glucose administration and insulin-induced hypoglycemia stimulate a release of growth hormone (GH) greater in patients with endometrial cancer than in control subjects. However, Brown[7] was unable to confirm this paradoxical rise of GH in response to hyperglycemia induced by oral glucose administration in endometrial cancer patients, nor was any abnormality of thyroid or adrenal function detected. However, Brown did find significantly lower plasma luteinizing hormone (LH) levels in endometrial cancer patients, leading him to suggest that insufficient LH secretion may be causally related to the frequent occurrence of ovulatory failure, decreased fertility, and prolonged unopposed estrogen stimulation of the endometrium. Benjamin and Deutsch,[8] on the other hand, found no difference in basal LH levels between endometrial cancer patients and control subjects but did find a significantly lower level of basal follicle-stimulating hormone (FSH) among the endometrial cancer patients.

This prospective study was designed to investigate carbohydrate metabolism and anterior pituitary function in a consecutive series of postmenopausel women with proved adenocarcinoma of the endometrium and to compare the results with the findings obtained in parallel studies in a group of age- and body weight–matched postmenopausal women known to be free of endometrial cancer.

Subjects and methods

Sixteen consecutive patients with adenocarcinoma of the endometrium and a control group of 16 women

From the Department of Reproductive Medicine, University of California, San Diego, School of Medicine.

who were 2 years or more postmenopausal, matched for age and weight, comprised the study populations (Table I). All the cancer patients had the diagnosis established by uterine curettage. Absence of endometrial carcinoma was confirmed by curettage or endometrial biopsy in all the control subjects. Eight of the 16 cancer patients had previously received estrogen for climacteric symptoms for 1 year or more. All hormonal medications had been discontinued at least 2 weeks before the initiation of this study. In addition all studies were repeated 8 to 12 weeks following completion of treatment. Three of 16 control subjects had received prior estrogen replacement therapy, which was discontinued at least 4 weeks prior to study. The protocol was approved by the Committee on Human Experimentation and informed consent was obtained from each subject.

Each subject was studied for 3 consecutive days, at bed rest, after an overnight fast, starting at 8:00 AM, according to the following protocol:

Day 1. Rapid intravenous glucose tolerance test, with 25 gm 50% glucose injected intravenously within 2

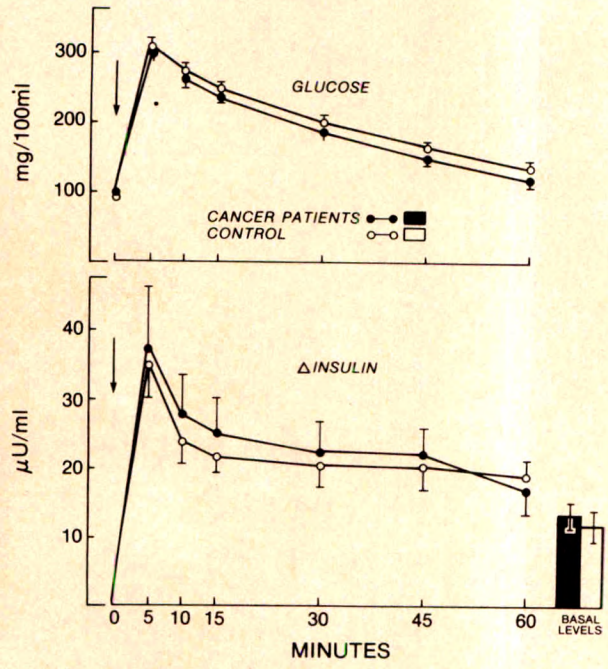

Fig. 1. Changes in plasma glucose concentration and net insulin secretion after 25 gm glucose intravenously.

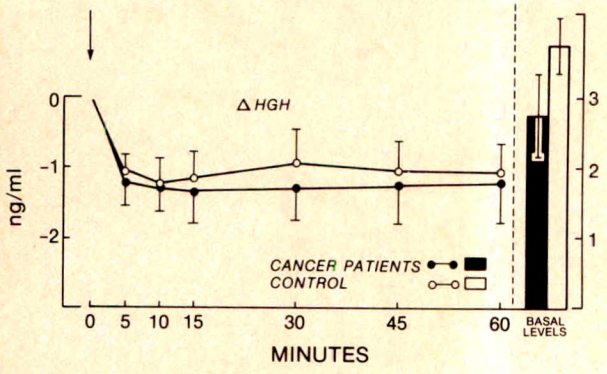

Fig. 2. Changes in GH secretion after 25 gm glucose intravenously.

minutes, and blood samples obtained at 0, 5, 10, 15, 30, 45, and 60 minutes.

Day 2. Arginine infusion, 0.5 gm/kg body weight, infused over a 30 minute period, and blood samples obtained at 0, 30, 60, 90, and 120 minutes.

Day 3. Insulin tolerance test, with 0.1 U regular insulin/kg body weight injected intravenously and blood obtained at 0, 30, 60, 90, and 120 minutes.

True plasma glucose levels were measured by Auto-Analyzer. Serum was separated and frozen at 20° C for subsequent measurement of LH, FSH, prolactin (PRL), GH, insulin, estrone (E_1), and estradiol (E_2), utilizing radioimmunoassay techniques.[9–12]

The blood glucose disappearance rate was defined as the K value, or mg/100 ml/min decline in blood glucose level following the rapid intravenous injection of 25 gm glucose. A K value of less than 1.0 indicates diabetes, 1.0 to 1.1 is considered borderline, and a value greater than 1.1 is considered normal.

Results

Baseline hormone data. The individual and the mean (±standard error) fasting plasma hormone levels on each of 3 consecutive days are shown in Table II. There were no significant differences between the cancer and control groups for any of the hormones measured.

Intravenous glucose tolerance test. The glucose response curves following 25 gm glucose given intravenously are identical in cancer patients and control subjects (Fig. 1). The mean ± standard error of the K value for the two groups is presented in Table II. Two patients in the control group and one in the cancer group had K values below 1.0, in the diabetic range. There was no significant difference between the means of the groups.

The changes in insulin and GH levels after intravenous glucose loading also show no significant differences between the two groups at any of the time periods (Figs. 1 and 2).

Arginine infusion. The fasting preinfusion levels of GH was lower in the cancer group ($p < 0.05$). However, following arginine infusion there were no significant differences in the net rise in GH or insulin levels between the cancer and control groups at all time intervals studied (Fig. 3).

Intravenous insulin. The peak hypoglycemic response to insulin (0.1 U/kg) was identical in the two groups (Fig. 4). At 90 and 120 minutes after the injection of insulin the recovery from hypoglycemia was more rapid among the control subjects ($p < 0.05$). The fasting GH level was lower in the cancer patient group ($p < 0.05$). However, there were no significant differences in the ΔGH response to hypoglycemia between the two groups (Fig. 4).

Effect of previous estrogen replacement therapy. Comparisons were made of all baseline hormone levels, response curves to arginine, hyperglycemia and hypoglycemia, and intravenous glucose tolerance between patients who had previously received exogenous estrogen therapy and those with no history of estrogen therapy. As noted, all hormonal medication had been discontinued 14 to 35 days before the initial study. In addition all 16 cancer patients were restudied for 3 days 8 to 12 weeks after completion of treatment, at which time no patient had received exogenous estrogen for over 10 weeks. No significant differences in any of the studies described above were found between the

prior estrogen therapy and no estrogen therapy groups, either (1) within the cancer patient group, (2) when all subjects who had received estrogen (N = 11) were compared with all subjects who had not received estrogen (N = 21), or (3) when cancer patients never given estrogen (N = 8) were compared to control subjects never given estrogens (N = 13). These data will be the subject of a separate report.

Correlation between baseline levels of estrogen, GH, and PRL. No correlation was found between baseline levels of E_1 and E_2 and either GH or PRL in either group (cancer group E_1 plus E_2 versus GH and versus PRL, r = 0.136 and −0.172; control group E_1 plus E_2 versus GH and versus PRL, r= 0.224 and −0.080).

Comment

Data in the literature present conflicting results with regard to most of the studies reported above.[1–8] Thus there is no uniformity of data to support carbohydrate intolerance or abnormal basal levels of any pituitary hormone or of estrogens, androgens, or adrenal corticosteroids in patients with endometrial adenocarcinoma. Controversy also exists regarding reported abnormalities of GH responses to hyperglycemia, hypoglycemia, and arginine infusion, as well as for insulin response to hyperglycemia and arginine.

The most convincing data supporting an abnormality of endocrine function are from studies of estrogen and androgen metabolism in obese patients with adenomatous endometrial hyperplasia and adenocarcinoma. There is impressive evidence that an excess of estrogen, primarily estrone, is produced via peripheral aromatization of androstenedione by obese postmenopausal women with endometrial hyperplasia or cancer.[13–19] McDonald and colleagues[13] indicate that obesity is the common denominator, since conversion of androstenedione to estrone is elevated in obese postmenopausal women whether or not endometrial hyperplasia or neoplasia exists.

In the present study all subjects were at least 2 years postmenopausal, with a mean age equivalent to the mean age reported in most epidemiologic studies of endometrial cancer.[1, 2] Obesity was not a significant feature in this group of patients. In fact the modest mean excess of weight over "ideal" weight (computed using Metropolitan Life Insurance Company height-weight tables) is compatible with the norm for a postmenopausal middle-income female Caucasian population in the United States. The results, therefore, are a comparison of the specified endocrine and metabolic indices in a well-defined patient and control population where obesity was not a significant factor.

Within this context, the striking finding is the simi-

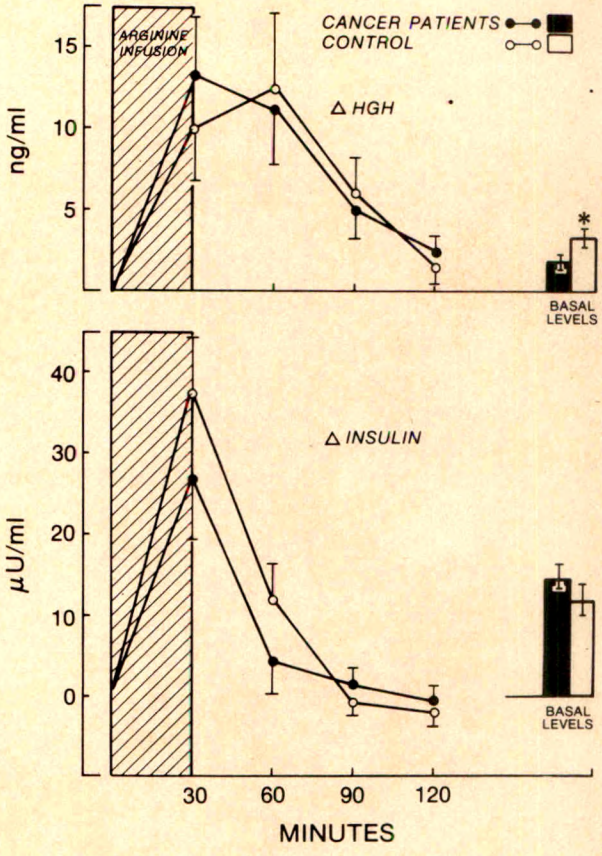

Fig. 3. Net changes in GH and insulin secretion after arginine infusion (0.5 gm/kg body weight).

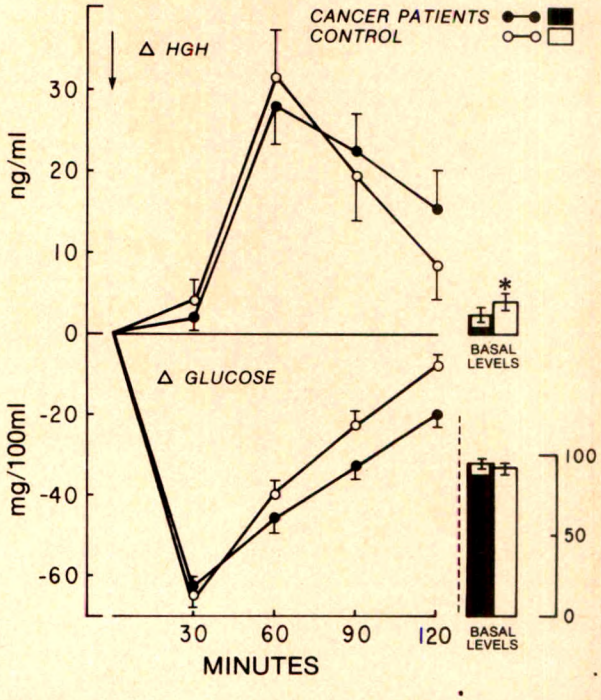

Fig. 4. Net changes in GH secretion and plasma glucose concentration after intravenous insulin (0.1 U/kg body weight).

larity of all the baseline hormone levels. In addition, hyperglycemia-, hypoglycemia-, and arginine-induced changes in GH secretion and hyperglycemia- and arginine-stimulated changes in insulin secretion were comparable between the two groups of subjects.

This study fails to support observations that abnormal GH secretion occurs in response to hyperglycemia or hypoglycemia in postmenopausal endometrial cancer patients.[5, 6]

Brown[7] reported that circulating and urinary LH levels were lower in endometrial cancer patients than in control subjects. Concomitant measurements of FSH or estrogen levels were not performed. It is inappropriate to assign any pathophysiologic significance to low LH values found in cancer patients unless the aforementioned interrelated hormones are analyzed together.[20] Nonetheless, neither observation, that baseline LH levels are significantly lower in endometrial cancer patients than in control subjects[7] or that FSH levels are significantly lower in endometrial cancer patients,[8] is supported by our data.

The similarity of serum E_1 and E_2 levels between cancer and control subjects corroborates the findings of Rader and associates[21] and a previous report from this laboratory.[22]

There was no alteration in insulin sensitivity (Fig. 3) and no increase in carbohydrate intolerance, as measured by insulin-induced hypoglycemia and a standard intravenous glucose loading technique, in the cancer patients. In fact, using a K value of less than 1 as the criterion of diabetes, three of the control subjects and only one of the cancer patients were diabetic.

An absence of any demonstrable effect of prior estrogen replacement therapy (0.625 to 1.25 mg of conjugated estrogens daily) on carbohydrate tolerance or fasting hormone levels was noted. Spellacy and associates[23] could find no effect of 1.25 mg of Premarin daily for 1 year on plasma insulin, GH, or triglyceride levels. They did note, however, an elevation of blood glucose at 1 hour during an oral glucose tolerance test compared to the preestrogen test. Hammond and associates,[24] in a retrospective comparison of 301 women on a regimen of estrogen replacement therapy for ovarian failure of a variety of causes with a matched group not receiving estrogen found no difference in the occurrence rate of any endocrine disorder during the 5 year study period. In fact, there was a lower occurrence rate of diabetes in the estrogen-treated group during the study period.

In conclusion, rather than supporting the existence of disorders of hypothalamic-pituitary function in patients with endometrial adenocarcinoma, this study suggests an absence of significant deviations from the usual postmenopausal endocrine state. We are left with the statement made by Wynder and co-workers[2] over a decade ago that "It is apparent that the primary problem of the endometrial cancer patient is obesity."

Even though the obesity-related "unopposed estrogen" hypothesis as an important factor in endometrial carcinogenesis is increasingly supported by convincing data,[13, 18] it fails to account for the not infrequent patient with endometrial cancer who is not obese, has borne children, and has never received estrogens. To date excess estrogen production or abnormal metabolism has not been observed in this group of "normal" postmenopausal women who develop endometrial cancer. This together with our present findings indicates a significant subgroup of patients in whom no discernible metabolic or endocrine abnormalities have been conclusively identified. The complexity of finding the cause, or causes, of a given cancer is re-emphasized.

Discussion

DR. BOYD C. QUINT, Seattle, Washington. Dr. Lucas and his associates have contributed enormously to our limited knowledge of endocrine and metabolic changes surrounding endometrial carcinoma and related disorders. His[1] superb monograph in the *Obstetical and Gynecological Survey* in 1974 elegantly summarized the world knowledge on endometrial carcinoma at that time. If you have not reviewed it recently, I would suggest you do so. In that paper he pointed toward areas where further study might help unravel some of the mysteries surrounding this puzzling disease. This current presentation is a step in that direction.

Dr. Lucas pointed out in his introduction that there have been conflicting reports on metabolic changes and hormone levels in endometrial carcinoma. His protocol is designed to very well resolve some of these conflicts. The simultaneous gathering of hormone levels and metabolic changes make these results all the more meaningful. The lack of significant differences between the control subjects and cancer patients in *all* areas studied is surprising. Their graphic portrayal is striking, dramatic, and convincing. These results most effectively resolve the conflicting and contradictory reports he cites in the literature. At least in nonobese patients, we must look elsewhere for answers to the etiology of this enigmatic disease. The absence of differences in estrogen users and nonusers, regardless of group, I find particularly intriguing and look forward to Dr. Lucas's forthcoming report on this subject.

The other area considered most promising in the investigation of the etiology of this disease is the study of estrogen receptor sites. A number of studies have appeared on this subject in the recent literature.[2–7] Unfortunately, so far they face us with as much confusion as in previous hormonal studies. I have summarized

Table I. Estrogen receptor levels

Type of endometrium	*Evans and associates*[2]	*Pollow and associates*[3]	*Friberg and associates*[4]	*Crocker and associates*[5]	*Gurpide and associates*[6,7]
Proliferative	High, decreasing through cycle	High	Not treated in paper	Maximal at ovulation	High, decreasing through cycle
Secretory	Low	Low	Not treated in paper	Maximal at ovulation	Low
Adenomatous hyperplasia	High	–	Not treated in paper	–	High
Well-differentiated adenocarcinoma	Higher	Lower	Higher	No correlation with degree of differentiation	Moderate
Poorly differentiated adenocarcinoma	Lower	Higher	Lower	No correlation with degree of differentiation	Moderate

several of these reports in Table I. Three of four reports agree that receptor sites are high in normal proliferative endometrium and low in secretory endometrium. However, the fourth states they are maximal at ovulation. Both investigators reporting on adenomatous hyperplasia agree that levels here are high. The picture surrounding carcinoma is particularly blurred, as you can see. Two reports cite higher levels with well-differentiated tumors, approaching that of proliferative endometrium; one states the reverse, and the others take the middle ground. Hopefully, Dr. Lucas and his associates can generate the same sort of painstaking protocol to resolve these differences.

I have two questions to ask Dr. Lucas. What were the pathology reports on his patients? He makes no mention of degree of differentiation of the tumors of his cancer patients, whether or not their tumors were invasive, or if there were metastases. Second, had any patients in either group received oral progestins?

This is a most significant, sound paper in an area where clarification is sorely needed.

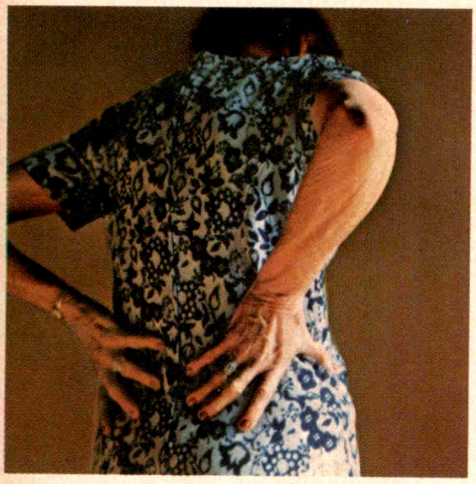
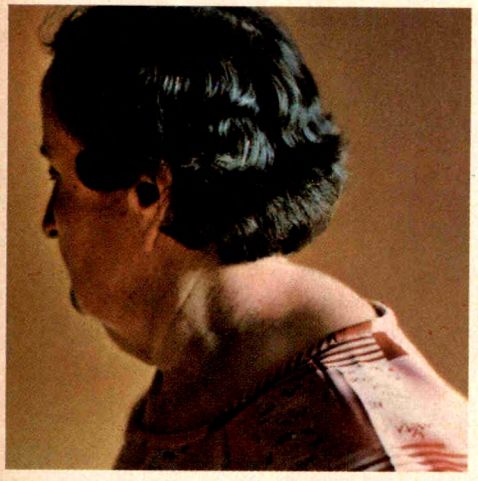
Dr. Gilbert A. Webb, San Francisco, California. What were the ages at menopause in patients with carcinoma of the endometrium and in the control group? The subgroup referred to is an increasing one, at least as we have observed and I believe this was also mentioned by Smith. There is an increasing number of patients with adenocarcinoma of the endometrium who do not have hypertension and are not obese and who have had children, and I wondered if the age at menopause might be a significant factor.



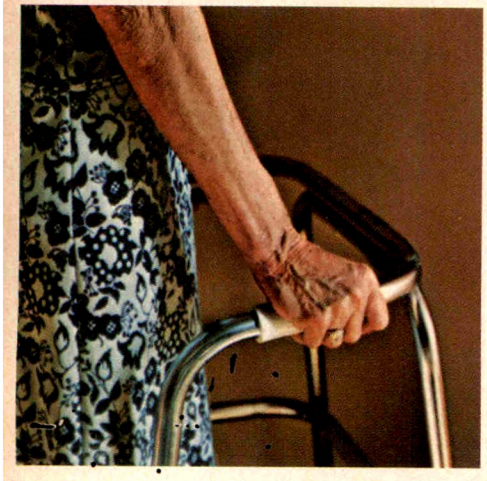
Dr. Lucas (Closing). Estrogen receptor study relative to endometrial cancer is in its infancy compared to that relative to breast cancer. Obviously, a great deal more work needs to be done in this area. By and large, one can say that there are many more similarities than differences between normal endometrium and carcinomatous endometrium, at least in its early stages, and this also is true of progesterone receptor studies. These patients all had Stage I, either A or B, adenocarcinoma of the endometrium. All had grade 1 or 2 lesions; there were no grade 3 cancers in the group. They provided the usual spectrum of pathology that one sees in a consecutive group of patients with adenocarcinoma of the endometrium. The slides in each case were re-reviewed to confirm the original diagnosis. None of these patients had received oral progestins. But I should mention parenthetically that of our 16 endometrial cancer patients, following completion of the original studies, half of the group then received high doses of Depo-Provera prior to surgery, usually during the 4 week period that they were receiving external irradiation. This did produce some interesting findings which will also be the subject of a subsequent report.

All of these patients were at least 2 years postmenopausal. I am sorry I cannot answer the question as to whether or not menopause was later compared to the overall population, but they were not as compared to the control group. As a matter of fact, the age of menopause was a little later in the control group than in the endometrial cancer group.

Postmenopausal women can lose more than estrogen...



because osteoporotic bone loss* can lead to pain... muscle contracture... and other sequelae

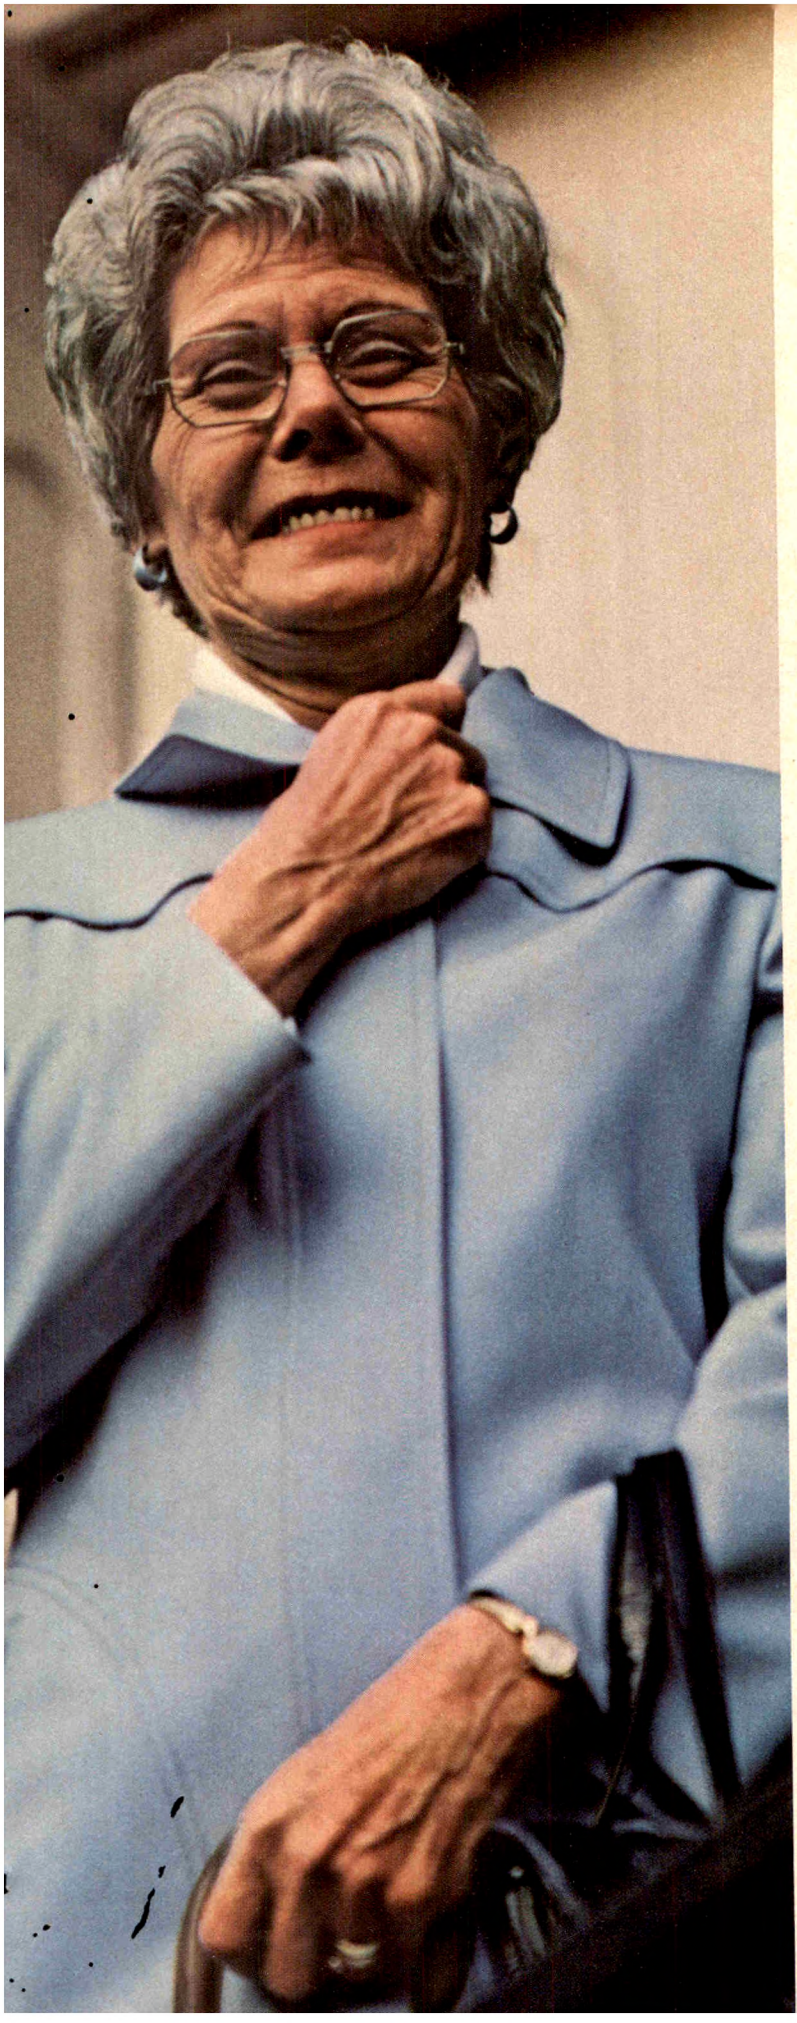


PAIN:
THE FIRST STEP IN A LONG PROGRESSION.

Postmenopausal bone loss typically progresses from "silent" symptoms to more obvious signs. Significant loss of bone tissue eventually produces thinned, weakened vertebrae that, in weight-bearing areas, may cause low back pain, typically nonradiating in nature.

THE SPINE:
A LONG-TERM TARGET.

It is not uncommon for these osteoporotic changes to lead to loss of height, with accentuated spinal curvature. In more advanced cases, the vertebrae may exhibit signs of biconcavity, collapse, and wedging.



THE YOUNGER HYSTERECTOMY/ OOPHORECTOMY PATIENT— A PARTICULARLY VULNERABLE CANDIDATE.

With the prospect of prolonged estrogen deprivation and its consequences, the younger woman whose uterus and ovaries have been removed runs the greater risk of developing extensive loss of bone mass. But even if the ovaries are conserved at the time of hysterectomy, the eventual onset of natural menopause may lead to symptoms of bone loss requiring treatment.

*Conjugated Estrogens Tablets have been evaluated as probably effective for postmenopausal osteoporosis. See Prescribing Information.

effective replacement therapy should retard progression*... promote good management

Recent findings indicate that the rate of bone loss in postmenopausal women is not correlated with age but with time after menopause, and that estrogen replacement therapy significantly retards bone loss. This holds true for both the natural and the artificially induced menopause. PREMARIN (Conjugated Estrogens Tablets, U.S.P.), in conjunction with other standard measures (such as diet, calcium, and physiotherapy), can often play a significant role in retarding the loss of bone mass and minimizing such sequelae as pain, loss of height, and kyphosis.

1/ The cyclic administration of 0.625 mg or 1.25 mg of PREMARIN daily is recommended to control progression.

2/ PREMARIN should be administered cyclically even in the hysterectomized patient. Follow-up is indicated to determine a continuing need.

*Conjugated Estrogens Tablets have been evaluated as probably effective for postmenopausal osteoporosis. See Prescribing Information.

for those women who should have estrogen

PREMARIN®
(CONJUGATED ESTROGENS TABLETS, U.S.P.)
0.3mg/0.625mg/1.25mg/2.5mg

Please see next page for brief summary of prescribing information.

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULAR)

PREMARIN® Brand of Conjugated Estrogens Tablets, U.S.P.

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year.[1-3] This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.[4] The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment[1] and on estrogen dose.[3] In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration;[3] it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare.[5,6] This risk has been estimated as not greater than 4 per 1000 exposures.[7] Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis,[8-12] epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects.[13-16] One case control study[16] estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (Conjugated Estrogens Tablets, U.S.P.) for oral administration contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters.

INDICATIONS: Based on a review of PREMARIN Tablets by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications for use as follows:

Effective:

1. Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms, and they should not be used to treat such conditions.)
2. Atrophic vaginitis.
3. Kraurosis vulvae.
4. Female hypogonadism.
5. Female castration.
6. Primary ovarian failure.
7. Breast cancer (for palliation only) in appropriately selected women and men with metastatic disease.
8. Prostatic carcinoma—palliative therapy of advanced disease.
9. Postpartum breast engorgement—Although estrogens have been widely used for the prevention of postpartum breast engorgement, controlled studies have demonstrated that the incidence of significant painful engorgement in patients not receiving such hormonal therapy is low and usually responsive to appropriate analgesic or other supportive therapy. Consequently, the benefit to be derived from estrogen therapy for this indication must be carefully weighed against the potential increased risk of puerperal thromboembolism associated with the use of large doses of estrogens.[19]

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

"Probably" effective: For estrogen deficiency-induced osteoporosis, and only when used in conjunction with other important therapeutic measures such as diet, calcium, physiotherapy, and good general health-promoting measures. Final classification of this indication requires further investigation.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (See Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: At the present time there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast,[17] although a recent study has raised this possibility.[18] There is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.[17]

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement.[19-22] Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction.[23-30] Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users.[31,32] An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives.[33,34] If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown[35] to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives.[36] Increased blood pressure may occur with use of estrogens in the menopause[37] and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Oral contraceptives appear to be associated with an increased incidence of mental depression.[23a] Patients with a history of depression should be carefully observed. Preexisting uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not complete.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome, amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair, hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION: 1. *Given cyclically for short term use only:* For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 to 1.25 mg or more daily).

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (*e.g.*, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three to six month intervals.

2. *Given cyclically:* Female hypogonadism. Female castration. Primary ovarian failure. Osteoporosis.

Female hypogonadism—2.5 to 7.5 mg daily, in divided doses for 20 days, followed by a rest period of 10 days' duration. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium.

If bleeding occurs before the end of the 10 day period, begin a 20 day estrogen-progestin cyclic regimen with PREMARIN (Conjugated Estrogens Tablets, U.S.P.), 2.5 to 7.5 mg daily in divided doses, for 20 days. During the last five days of estrogen therapy, give an oral progestin. If bleeding occurs before this regimen is concluded, therapy is discontinued and may be resumed on the fifth day of bleeding.

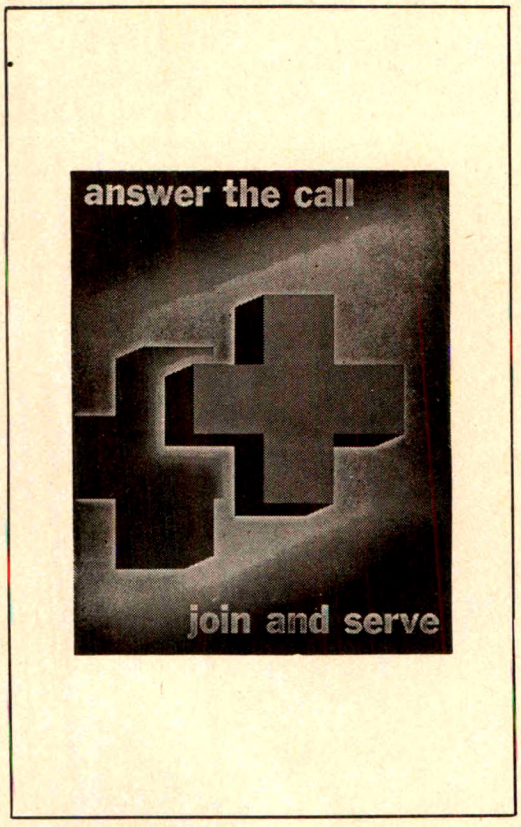
Female castration and primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis (to retard progression)—1.25 mg daily, cyclically.

3. *Given for a few days:* Prevention of postpartum breast engorgement—3.75 mg every four hours for five doses, or 1.25 mg every four hours for five days.

4. *Given chronically:* Inoperable progressing prostatic cancer—1.25 to 2.5 mg three times daily.

Inoperable progressing breast cancer in appropriately selected men and postmenopausal women—10 mg three times daily for a period of at least three months.



Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED: PREMARIN (Conjugated Estrogens Tablets, U.S.P.) No. 865—Each *purple* tablet contains 2.5 mg in bottles of 100 and 1,000. No. 866—Each *yellow* tablet contains 1.25 mg in bottles of 100 and 1,000. Also in unit dose package of 100. No. 867—Each *red* tablet contains 0.625 mg in bottles of 100 and 1,000. Also in unit dose package of 100. No. 868—Each *green* tablet contains 0.3 mg in bottles of 100 and 1,000.

Ayerst. AYERST LABORATORIES
New York, N.Y. 10017

1979 ORIENT TOURS

For Doctors Attending Tokyo, Oct. 25-31, IXth World Congress of Gynecology and Obstetrics

$544 **TOTAL ROUNDTRIP AIRFARES**
Los Angeles/San Francisco - Tokyo
Land services NOT necessary to qualify

Oct. 21-31: On **scheduled** jumbo jet flights of scheduled airlines at lower airfares than on known charter flights. **No land arrangements necessary.** Only 50 doctors with six or more months membership in American Medical Association or American College of Obstetrics and Gynecology, with their wives, will qualify either group of 100 eligible people for these very low airfares.

ALSO AVAILABLE

Tours combining airfares with land arrangements. Very highest quality throughout, such as deluxe and top first-class hotels, and in certain tours extensive sightseeing, dinner parties, and folklore shows to assure that you will enjoy the Orient, not just see it.

TOKYO ONLY—$899—Oct. 21-31—11 days
For doctors concentrating their time on the medical sessions in Tokyo who desire only airfares, hotel, and transfers.

JAPAN ONLY—$1099—Oct. 21-31—11 days
For doctors unable to be absent from their practices very long who want to visit the classical city of Kyoto, in addition to Tokyo.

TOKYO-HONG KONG—$1249—Oct. 23-Nov. 5—14 days
Designed to enable doctors to concentrate their professional time at the medical sessions in Tokyo and enjoy vacation time in Hong Kong.

ORIENT HILITES—$1399—Oct. 23-Nov. 7—16 days
For doctors with limited time who want significant Orient coverage. Includes the "core" of the Orient: Japan, Taiwan, Philippines, Hong Kong.

ORIENT GRAND—$1849—Oct. 23-Nov. 12—21 days
Offers the ultimate, practically all of the Far East: Japan, Taiwan, Philippines, (Bali) Indonesia, Singapore, Thailand, Hong Kong. If you have time, this is the program for you.

Apply: HOWARD TOURS, INC.
526 Grand Avenue; Oakland, California 94610
Telephone: (415) 834-2260

NOW YOU CAN MOVE UP WITHOUT MOVING OUT.

The Air Force has a new Hometown Assignment Program for physicians. If you have the right specialty and if you live in or near a city where an Air Force hospital is located, you could qualify.

You would receive a direct commission, possibly as high as Lt. Colonel, and all the benefits of an Air Force Officer. At the same time you could maintain your present home. Your children could stay in the same schools. You could even have 30 days of vacation with pay each year. Or if you want a change of scenery, the Air Force could possibly assign you to the base of your choice.

Here's what you would *lose.*

You wouldn't have to pay malpractice insurance. "Boss" an office staff. Or worry about the thousands of details a small businessman has to deal with.

You could concentrate on practicing medicine.

Get all the details. Talk to your Air Force Recruiter. Or mail in this coupon or call toll free 800-523-5000 (PA: 800-362-5696).

A GREAT WAY OF LIFE.
AIR FORCE

A Major Breakthrough from Sandoz Research

Parlodel®
(bromocriptine mesylate)

TABLETS, 2.5 mg.

The first clinically useful dopamine receptor agonist

Dosage and Administration

- Start with one 2.5-mg tablet with the evening meal for three days; increase to one tablet with food in the morning and in the evening on the fourth day. The therapeutic dosage is one tablet two or three times daily with meals.
- If adverse effects occur, temporarily reduce dosage.
- Duration of treatment should not exceed six months.
- If pregnancy occurs, treatment should be discontinued immediately.
- For further details, including information on contraception and pregnancy tests, please see Brief Summary.

Contraindications: Sensitivity to any ergot alkaloids.
Warnings: Since hyperprolactinemia with amenorrhea/galactorrhea has been found in patients with pituitary tumors (Forbes-Albright syndrome), a complete evaluation of the sella turcica is advisable before treatment with Parlodel® (bromocriptine mesylate). Although Parlodel therapy will effectively lower plasma levels of prolactin in patients with pituitary tumors, this does not obviate the necessity of radiotherapy or surgical procedures where appropriate. If pregnancy occurs, treatment should be discontinued immediately; safe use has not been demonstrated in pregnancy. Should not be administered to nursing mothers. Safety and efficacy have not been established in children under age 15. Although the incidence of congenital malformations and spontaneous abortions reported in human studies does not exceed that generally reported for such occurrences in the population at large, the total numbe

- mimics the action of dopamine at the receptor sites
- potent inhibitor of prolactin secretion
- indicated in amenorrhea/galactorrhea associated with hyperprolactinemia*

Clinical effectiveness in amenorrhea/galactorrhea associated with hyperprolactinemia*

Parlodel therapy was studied in 210 patients with amenorrhea/galactorrhea associated with hyperprolactinemia;* of whom 187 were evaluated for efficacy. In light of the usual findings with previously available therapies, the response to Parlodel® (bromocriptine mesylate) was impressive.

- **CLINICAL IMPROVEMENT IN AMENORRHEA**
  Reinitiation of menses (or pregnancy without first having menses†) was reported by 80% of 187 patients after an average treatment time of 5.7 weeks.

- **CLINICAL IMPROVEMENT IN GALACTORRHEA**
  76% of 187 patients experienced clinically significant—75% or greater—reduction in galactorrhea, and 58% experienced complete cessation of milk secretion. The treatment time required for 75% reduction was 6.4 weeks, and that for complete cessation was 12.7 weeks.

- **OVERALL CLINICAL EFFECTIVENESS**
  63% of 187 patients experienced reinitiation of menses and at least 75% reduction in galactorrhea; 47% had both reinitiation of menses and complete cessation of milk secretion.

- **CORRELATION OF CLINICAL RESPONSE WITH REDUCTION IN PROLACTIN LEVELS**
  Improvement markedly correlated with reduction in serum prolactin levels. Maximum reduction of prolactin levels was achieved within the first four weeks of therapy, and reduced levels were maintained throughout therapy.

***in the absence of demonstrable pituitary tumor. Not indicated in patients with normal prolactin levels. Safe use in pregnancy not demonstrated. Thus, not indicated in the management of infertility.**
†Parlodel (bromocriptine mesylate) is not indicated in the management of infertility.

Stylized rendition of the hypothalamus and the pituitary

©1978 Sandoz, Inc.

of pregnancies reported is an insufficient sample in which to detect any given birth defect; extrapolation of these data to a greater patient population would be statistically invalid.
Precautions: Since treatment may result in restoration of fertility, patients should be required to use contraceptive measures, other than the oral contraceptives, during treatment; however, since patients often ignore this recommendation and since pregnancy may occur prior to reinitiation of menses, as an additional precaution, a pregnancy test is recommended at least every four weeks during the amenorrheic period and, once menses are reinitiated, every time a patient misses a menstrual period. Parlodel® (bromocriptine mesylate) therapy has been demonstrated to be effective in the short-term management of amenorrhea/galactorrhea only. Data are not available on the safety or effectiveness of its use in long-term continuous dosage, or in patients given repeated courses of treatment following recurrence of amenorrhea/galactorrhea after initial treatment. Recurrence rates are reportedly very high, ranging from 70% to 80% in domestic and foreign studies.
Adverse Reactions: The incidence of adverse effects is quite high (68%) but these are generally mild to moderate in degree. Therapy was discontinued in approximately 6% of patients because of adverse effects. These in decreasing order of frequency are nausea 51%, headache 18%, dizziness 16%, fatigue 8%, abdominal cramps 7%, lightheadedness 6%, vomiting 5%, nasal congestion 5%, constipation 3% and diarrhea 3%. A slight hypotensive effect may accompany Parlodel® (bromocriptine mesylate) treatment. The occurrence of adverse reactions may be lessened by temporarily reducing dosage to one-half tablet two to three times daily.
Dosage and Administration: The therapeutic dosage is one 2.5-mg tablet, two or three times daily, with meals. Duration of treatment should not exceed six months. It is recommended that treatment commence with one tablet daily, increasing to a therapeutic dosage within the first week, to reduce the possibility of adverse reactions.
How Supplied: Tablets, 2.5 mg, in packages of 30.

Before prescribing or administering, see package insert for full product information.

Saf-T-Coil®— in use for over 10 years

Saf-T-Coil is an IUD found comparable to the "pill" in use effectiveness.[1-2]

Five-year study[2] — 27,712 insertions — 541,248 women/months of use:

- a low 0.8% *in situ* pregnancy rate
- high 80% continuation rate
- 11.9% expulsion rate
- 8.0% removal rate

Subsequently, the investigators made Saf-T-Coil their "device of first choice."

1. Caraway, A.F.: Florida's Experience with an Intrauterine Device for the Nulliparous Patient. Presented at the International Family Planning Research Association Meeting, Palm Springs, California, October 21, 1974.
2. Caraway, A.F. and Vaughn, B.J.: J. Reprod. Med. *10*:170, April 1973.

Life table data — 46,721 women/months

Clinical trials were conducted with Saf-T-Coil in which use effectiveness was determined as follows for parous women, as tabulated by the life table method.[3-7] This experience is based on 46,721 women/months of use including 4,231 women who completed 12 months of use and 1,842 women who completed 24 months of use. Rates are expressed as events per 100 women through 12 and 24 months of use.

	12 Months	24 Months
Pregnancy	2.4 (0.42-2.8)	3.1 (0.42-3.8)
Expulsion	18.3 (7.8-29.0)	18.8 (9.0-21.5)
Medical Removal	15.6 (4.8-18.7)	23.2 (9.0-27.0)
Continuation Rate	70.4 (55.2-88.0)	59.8 (57.0-81.5)

7. Tietze, C.: Report of a New IUD: The Double Coil. Advances in Planned Parenthood, III:85, 1967.

Three Saf-T-Coil sizes ensure contraceptive effectiveness throughout her reproductive years: Saf-T-Coil Nullip 25-S for the nulliparous and young woman, Saf-T-Coil 32-S for the primiparous woman and Saf-T-Coil 33-S for the multiparous woman.

Every Saf-T-Coil is made of inert plastic with no copper additives. And with every Saf-T-Coil — Saf-T-Sound® — the sterile, disposable intrauterine probe that helps make fitting easier and more accurate.

Caution: Federal law restricts this product to sale by or on the order of a physician.
Contraindications: Should not be used in: pregnancy or suspicion of pregnancy; abnormalities of the uterus resulting in distortion of the uterine cavity; acute pelvic inflammatory disease or a history of repeated pelvic inflammatory disease; postpartum endometritis or infected abortion in the past three months; known or suspected uterine or cervical malignancy including unresolved, abnormal "Pap" smear; genital bleeding of unknown etiology; untreated acute cervicitis until infection is controlled.

Saf-T-Coil®

SCHMID LABORATORIES, INC.

Health care: An enigma

ERVIN E. NICHOLS, M.D.
Washington, D. C.

IN THIS YEAR 1978, American medicine has reached goals seen unobtainable 40 years ago. The perinatal mortality rate continues to decline, death from carcinoma of the uterus is less frequent, and our female population is living longer. Yet medicine and, particularly, the discipline of obstetrics and gynecology are under ever-increasing attack.

The federal government is moving decisively in many areas relating to the practice of obstetrics and gynecology and is threatening further action in areas that have traditionally been under the direction of the profession. These actions have a direct effect on how physicians will practice their profession.

The Department of Health, Education, and Welfare has directly promulgated regulations that restrict a physician's actions in relation to sterilization and abortion.

An agency of the Department of Health, Education, and Welfare, the Food and Drug Administration, impacts on the practice of obstetrics and gynecology by inserting itself between the patient and her physician with the introduction of mandatory patient package inserts. In changing the labeling on oxytocin, this same agency has directly become involved in the setting of criteria for the practice of obstetrics and gynecology.

The use of pelvimetry, sonography, and mammography is currently being studied and evaluated by several governmental agencies—the Office of Environmental Health, the Bureau of Radiological Health, and the National Cancer Institute.

Controls have been placed on medicine by the Federal Trade Commission. By forcing consent decrees, some state medical associations and national specialty associations have had to withdraw relative value studies. It is ironic that at the time these actions are being pushed by the Federal Trade Commission requests are coming from the Department of Health, Education, and Welfare asking for fee schedules. Profiles are being assembled and it is predicted that all fees will be in a schedule in the near future.

During this same period of time, the legislative bodies of the federal government have also been active in appraising the practice of obstetrics and gynecology. One of the most important committees in the Senate has invested many hours of (nonmedical) staff time and a day in hearings assessing various aspects of obstetric practice—drugs, induction of labor, fetal monitoring, and cesarean section.

Another congressional committee has devoted much time and attention to the question of consultation prior to elective surgery with the result that there is now a section in the Department of Health, Education, and Welfare devoted solely to the planning and implementing of a program in this area.

As one looks at the activities of the various governmental bodies as they relate to health care, it becomes apparent that obstetrics and gynecology is a discipline that is heavily impacted by these actions. The question is asked why, with continuing better outcomes, are there increasing challenges to the care of obstetrics and gynecology patients by federal agencies?

This enigma (ever-better results and at the same time increasing restrictions and controls) calls for an assessment of the possible reasons why and consideration of programs for action that will maintain the forward progress in the health care of women and newborn infants.

In evaluating the reasons for legislative or regulatory actions in health care, several factors become evident. Cost is an item that transcends most actions even though often masqueraded under the guise of quality of care. Another source of activity is initiated by a small group of extremely vocal citizen activists. Mr. Nader with his Health Research Group plays a part in this scene. Health care is an issue that has strong political appeal in that it gives great visibility and provides a vulnerable target.

The activists are motivated for several reasons—some are plainly unhappy, a result of their relationship with the provider, and some have had a bad result. The

Presented at the Forty-fifth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Gleneden Beach, Oregon, September 26-30, 1978.

movement for home delivery is stimulated by some of these unhappy patients. They are some of the same people pushing to change regulations to allow more professionals into the system.

The same people reputedly representing various organizations, whose constituency cannot be identified, participate in many hearings relating to the discipline of obstetrics and gynecology. They have also been influential in stimulating oversight hearings both at the legislative and administrative levels.

The last several years could be characterized as a time of cost accountability. For the past decade, Congress has increasingly passed legislation that has constantly enlarged the base of spending for health. As the base is continually broadened and the desire for tax restraint becomes more popular, someone is caught in the middle.

During this present administration, there have been ever-increasing attacks and pressures on the health providers, particularly in relation to reimbursement. Secretary of Health, Education, and Welfare Califano has continued to crusade against the present system. An ominous storm warning is the abrupt firing of Robert Derzon, Administrator of the Health Care Financing Administration. Mr. Derzon was given the task of making medicaid and medicare work. It is the opinion of many in the health field that he was a person with excellent credentials for the task assigned. Unrealistic demands for cost containment resulted in confrontation. It is reported that when congress did not pass legislation putting a cap on hospital costs, there was a push to have this done by regulation. Mr. Derzon is alleged not to have responded fast enough. The issue is cost containment versus patient care. Without a doubt the cost of delivery of health care will be a priority item for both the congress and administration in the next decade.

The problem having been posed, it seems appropriate to look at some possible remedial actions.

It is time to consider the requests of patients for changes that are not detrimental to the health of themselves or their newborn infants. An example is the consideration of providing family-centered delivery programs in the hospital setting. Community involvement in the planning of such a program can do much to reduce the barriers and tensions that are present between the provider and patient.

The incorporation of nurse-practitioners into the system will do much to fill the gap between supply and demand in special situations such as large geographic areas with small patient populations. The nurse-practitioner can function well in busy urban centers where large demands result in delayed appointments, a source of major discontent.

The target at present is cost and almost every legislative or regulatory action has cost as the primary factor or it is disguised under such terms as "quality of care," "indices for care," or "outcome audit." Cost has become the "Holy Grail" of this era. The just-launched program by the Department of Health, Education, and Welfare "second opinion" is a classic example. No matter how it is camouflaged it is an attempt at cost control. Here again is an example of government (Mr. Califano) plunging ahead with a major program without any realistic testing.

Two areas in the discipline of obstetrics and gynecology are under scrutiny, hysterectomy and cesarean section. Cesarean section is now being investigated by congressional staffs, by the Federal Trade Commission, and by agencies of the Department of Health, Education, and Welfare. There are several contracts with nonmedical groups investigating cesarean section. The reason is the rate, which then can be related to cost.

If a national cesarean section rate of 25% is appropriate then it must be justified. The best figures for 1977 put the national rate at just under 13%. Assuming a total birth number of 3 million the difference in the number of cesarean sections between 13% and 25% is 360,000. Conservative estimates say that the expenditure for a cesarean section is at least $1,000 more than the expenditure for a vaginal delivery. This then brings a new expenditure of $360 million. Congress will look at $360 million. Is the additional expenditure justified? Without a doubt it is if there are better results. It is mandatory that hard data be made available very soon. How many neonates are saved by the higher cesarean section rate? What about morbidity? Does the fetal monitor increase the rate to an abnormally high figure? Is there good evaluation by peer review? Have preset criteria been established? These questions will have to be answered and a most important paper needed today is one with hard data on the subject "justification of cesarean section in 1979."

The past 40 years have shown tremendous improvement in the care and outcome of obstetrics and gynecology patients. As techniques improve, better results can still be anticipated. Continuous re-evaluation of these techniques is a must and hard data to present to cost-conscious legislative and regulatory bodies will do much to obtain their support for good obstetric and gynecologic care.

The agencies continue to write regulations and the congress continues to enact legislation. It is a daily, ongoing process. About 18 months ago, an office was es-

tablished in Washington to serve as a liaison between the legislative and administrative branches of government and the discipline of obstetrics and gynecology. There are increasing opportunities for cooperation and increasing amounts of participation in the planning phases of legislation and regulatory programs as they relate to obstetrics and gynecology.

The discipline must provide the solid data needed to justify current and future procedures. The physician must increase his or her efforts in communicating to and educating their patients and a major program of education and advocacy must be maintained at the legislative and regulatory levels. With these actions the scales will tilt toward better patient outcome. The goal of 10 in 10 is in sight.

Discussion

DR. KEITH P. RUSSELL, Los Angeles, California. *Webster's New Collegiate Dictionary* offers the following definitions of "enigma": 1. an obscure speech or writing; 2. something hard to understand or explain. In the present instance we can discard the first definition since what Dr. Nichols is telling us is not in the least obscure. However, he does present a finding that is "hard to understand or explain": the increasing governmental incursion into the health care field, usually on the basis of invalid patchwork information, biased testimony, and, frequently, undocumented pseudoscientific observations. At all levels of government, federal, state, and local, we find this same pattern characteristic of activities involving the health care field. There are multiple examples of the classic one cited by Dr. Nichols in which one branch of government states that a relative value schedule is "price fixing" but another program administered by the government requires a fee schedule. In essence, big government says that a required fee schedule is not price fixing but that a voluntary one is.

Another classic example is that of the position of the Federal Trade Commission (FTC) in regard to certification or accreditation activities. Here are some of the questions that the FTC is asking; listen carefully as that chairman speaks:

1. Do certification and accreditation standards establish only the minimum necessary to protect the public health and safety and to prevent fraud, or do they raise an excessive entry barrier? (In other words, are you as physicians attempting to keep the total number of doctors low to create an artificial shortage, thereby improving your own economic status?)

2. Do the standards required leave room for competing models of professional function? (That is, should inferior competing models be given an opportunity to lower standards simply because they are competing models?)

3. Is the accreditation function insulated from the officers and governing body of the association? (Thus, directors or officers of the organization cannot also be examiners or evaluators.)

4. Is the accreditation function insulated from the economic and political concerns of the members? (How can it be? To exist under government requires both economic and political concerns.)

5. Are competing interests given fair representation? (If an American Association for Humanities in obstetrics and gynecology is formed we must provide fair presentation for their representatives, regardless of their qualifications.)

This sort of activity is the essence of Dr. Nichol's essay. However, he quite rightly points out that there are always two sides to the coin. Our patient population does have changing interests and changing demands, often dictated by economic as well as political considerations. I certainly agree that we as physicians must adjust and adapt to these changes. This would imply, among other things he points out, the effective use of allied health personnel and alternative birth methods under physician supervision. Such utilization has been supported by the American College of Obstetricians and Gynecologists and was emphasized a number of years ago as one of the goals of the College.

I would like to reinforce two other remedial suggestions. One is the continued and extended attempts to educate the members of congress and administration to the true facts of medical practice; the second, a more intensive approach to consideration and review of the costs which we engender for the patients we serve. A key observation is that "if organized medicine wishes to remain free from governmental regulation, it must assume responsibility for the costs it generates." There are, without question, many areas in which a concerned analysis of the costs generated could lead to a reduction in and removal of excessive costs. This often must be done on a one-to-one basis but should have the support of our organized societies.

In closing, I will mention one other aspect which is not emphasized in Dr. Nichol's essay. It is related to the continuing malpractice problem. In my opinion, one reason for a rise in cesarean section rates in many areas can be found in the professional liability implications. As anyone knows who has dealt extensively with legal activity in the obstetric field, one of the major claims which frequently reaches trial court concerns the failure to perform cesarean section in cases where there is subsequent childbirth disability. The question a defendant doctor frequently must answer is why he did not perform a cesarean section. He seldom finds himself prosecuted for performing cesarean section, unless maternal death occurs or unless there is delay in performing the cesarean section. There is little question in

my mind that this is one of the factors which contributes to an increase in cesarean section rates as we presently see them.

I have enjoyed reviewing Dr. Nichol's paper; it is a concise commentary on the present Washington scene. We are indebted to him for this Washington update on an enigma with which he is highly familiar in his position as Director of the Washington office of the College.

DR. RAYMOND J. JENNETT, Phoenix, Arizona. I think in a meeting that has, to use Howard Cosell's phrase, been replete with excellent clinical papers, this has to stand as the most important one thus far heard, as far as its significance to health care. In its presentation Dr. Nichols dealt heavily with the question of cesarean section. Dr. Russell highlighted this, I think, with one very real reason as to why there might be an increase in cesarean sections. Dr. Nichols tells us that the General Accounting Office is going to be investigating us in this regard, and the key term he used throughout his presentation was "hard data" which is a term that I think falls rather strangely on our ears because, although we are presumably a scientific discipline, "hard data" are not really part of what we like to deal with. He has stated that a group in the State of Washington has been commissioned to determine why cesarean sections are done. I had the opportunity to talk to one of the doctors of philosophy from that group who, when asked to participate in the investigation, did what any proper doctor of philosophy would do, that is, called the head of a university obstetric department and was presumably told (leaving room for hyperbole reduction) that "if I could get the 'turkeys' in my department to write down why they do c-sections, I might be able to give you an answer to that question." So if there is anything that we have to do in our industry, which we are now being reduced to or forced into doing, it is to begin to become conscious of the necessity of collecting hard data. If we do not recognize this and demand that some of our patient dollars be spent on it, we will just be playing into the hands of what has been outlined to us. As I reported to this Society last year, in Arizona we have a statewide effort to do this and by the end of this year will have 60% of all births on a uniform perinatal record system, computer based. But our grant is going to run out and so we were asked by hospital administrators, "What is it going to cost to continue this?" When we told them $2.50 per patient the reaction was that this was an excessive cost. So I think we must recognize that this is not a priority among doctors or hospital administrators and demand that it must become a high one.

DR. CARL GOETSCH, Berkeley, California. One of the enigmas to which I feel we must seek some solution is the way in which government and even some among us look at the cost of medical care and the failure to analyze what makes up the cost. Paul Ward, who is now the Executive Director of the California Hospital Association, articulates this very well when he points out that the protest against the high cost of care is against the aggregate cost of medical care without a proper analysis as to what makes the aggregate so high. He points to two particular factors which are ignored by the Department of Health, Education, and Welfare and Secretary Califano and others. One factor is the enormous explosion in technology which has created the capacity for doing very expensive but often very productive testing and remarkable procedures that are lifesaving or capable of creating a significant increase in patient comfort. There is increasing demand by our patients for these. Such things as coronary bypass surgery, which is very, very expensive and becoming extremely popular, have caused a tremendous ballooning of medical costs, whereas the substructure of the fees for usual care has increased only at the rate of rising inflation or even, sometimes, less than that. The other factor that he points to is the enormous cost that is added because of defensive practices in respect to the professional liability problem. Yet the enigma to me is that the bureaucrats are looking at our fee structures, etc., and not paying attention to what the real causes are for this ballooning of the aggregate. It is important that we, when we make our presentations, try to point this out as loudly and as clearly as we can.

DR. MAX H. PARROTT, Portland, Oregon. Dr. Nichols' comments are pertinent. I would like to point out that I gave a paper in 1966, before this organization, in Santa Barbara under a euphemistic title, "Elective hysterectomy," in which many of the same socioeconomic facts were pointed out. In those days it was quite unusual to give a so-called socioeconomic paper before this organization. I think the goals of that type of paper have been borne out here by what Dr. Nichols has had to say. In that paper I made a plea, if you can remember, that the American Medical Association and the College get together for the development of hard data relative to elective hysterectomy.

The enigma is mostly a paradox promulgated by government. These paradoxes are an administrative insistence by the bureaucratic end of government to gain and maintain control.

I have just finished 2½ years as a chairman of a national commission on the cost of medical care. It was for this reason I was late to this meeting by a day and a half. They had their final meeting on Wednesday, September 20. They now have their three volumes published. There is a lot in this document, of course, that organized medicine will not buy. However, it points out the working problems that we have with the cost issue. I hope, and I have been assured both by Dr. Nichols and by the people in the Washington office of the American Medical Association, that these people in Washington are working closely in cooperation for all of us who practice medicine. I am certain they are. I might point

out that these same problems have been going on now for the extent of my existence in organized medicine, which is some 17 or 18 years. We still do not have that great center segment of American Medicine nationalized—that is, the people who basically pay for medical care, excluding the aged, the disabled, the destitute, and the children.

Again, I think that this is a timely paper. It is a paper that deserves serious consideration and I again plead for hard data. At one time I suggested to the Committee on Gynecologic Practice of the College that they do a study on the hysterectomized public of the United States as to patient satisfaction. I am so certain that this would be favorable to us within the specialty that I would be willing to take a chance on it. I think what Dr. Nichols is really getting around to is that we have done a good job in the practice of medicine and in the specialty of obstetrics and gynecology.

What we need and what we get are two different things. We should not be confused by what is said to be in our best interest. Beware of what is being done to you under the guise of something done for you. This applies to both physicians and patients.

DR. JOHN N. MILLER, JR., Sacramento, California. There are two items in the cost that need to be brought out. They are very important. When we talk about cost control, what we are talking about is rationing of medical care and it is just a matter of who is going to do it and how, and I recommend to you an excellent article on rationing in the *Center Magazine,* July-August, 1978, from the Institute of the Center for Democratic Institutions, in Santa Barbara. I think we ought to realize what the issue of rationing medical care involves. The item of cost is put into perspective in a recent article by the President of the California Medical Association. Medical care costs $160 billion a year. I think paper work costs $100 billion a year. The public is getting quite a bargain. The other aspect that Dr. Nichols did not speak to, but I think is critical, is the courts. There is a poorly recognized arm of the courts that has a great deal to do with the regulatory body, and these are the people who are going to be involved in the Food and Drug Administration and the Federal Trade Commission and these are administrative law judges who make some very significant decisions. The government has the money to handle the repeated appeals, but I do not think the private sector has quite those resources. The last, I think, is very appropriate. I encourage you, and each of you, that we do have a monitoring office in Washington, but each of you lives in a state, and you each have state legislators and governors, etc. So I encourage you to listen to what has been said and make an effort to be informed.

DR. NICHOLS (Closing). One thing I would like to bring out in Dr. Russell's comments, and it was brought up also by Dr. Miller, has to do with liability. I would call your attention to the oversight hearings on obstetric practice. This particular item of liability was very definitively brought out and, as a matter of fact, it was introduced by Senator Schweiker as we were presenting testimony. He asked the specific question as to what percentage we thought was due to the fear of liability. They know the problem. Dr. Jennett mentioned the General Accounting Office, and I can tell you that 3 days after the Senate hearings the General Accounting Office was in our office with four people, three young lawyers and a physician, and they were gathering data on how to approach this problem. So if they have not visited you and your various institutions yet, be assured that they are "coming down the pike." To reassure Dr. Parrott, I would like him to know that the office that was established in Washington and the office of the American Medical Association do cooperate. Having said that, I can only say that we do have a job and we must get to it.

Delivery of the tiny newborn

HANNS C. HAESSLEIN, M.D.
ROBERT C. GOODLIN, M.D.
Sacramento, California

Obstetric factors related to the survival of 100 newborn infants weighing between 800 and 1,350 grams were analyzed. Available data suggest that maternal intrapartum antibiotic and steroid administration and delivery by classical cesarean section are associated with increased newborn survival. (AM. J. OBSTET. GYNECOL. 134:192, 1979.)

THE RECENT SUCCESS of the neonatologists in sustaining life in the tiny premature infant has presented the obstetrician with the challenge of delivering these fragile infants in optimal condition. Newborn infants weighing less than 800 grams, unless growth-retarded, have negligible survival rates. Those weighing above 1,350 grams, when managed in level III intensive care nurseries, usually do well. At the University of California, Davis (UCD) Medical Center, Sacramento, an attempt was made to follow a relatively rigid intrapartum protocol for parturients between 26 and 31 weeks of gestation who were delivered of infants weighing between this critical 800 and 1,350 gram range. Presented below are the results and a discussion of the obstetric factors relevant to these tiny infants.

Material

The population analyzed consisted of 100 infants weighing between 800 and 1,350 grams born to 83 mothers at UCD Medical Center. Thirteen women were delivered of twins and two were delivered of triplets. Ten deliveries were performed because of severe maternal toxemia and three because of signs of Stage 0 abruptio placentae. The remaining 70 patients had premature labor and/or rupture of membranes.

Method

Upon admission to the labor ward, a general history was obtained, a physical examination was performed, and an estimate was made of the duration of pregnancy. If delivery was not imminent and the estimated fetal weight was between 800 and 1,350 grams, certain routine studies were done and patients were begun on the protocol shown in Fig. 1.

An ultrasonic B-scan was obtained for estimation of fetal age and to rule out multiple gestation. An x-ray film was also obtained if there was any suggestion of fetal abnormality or abnormal fetal position. If the membranes were ruptured, amniotic fluid from the posterior fornix was obtained for a lecithin/sphingomyelin (L/S) ratio and bacterial cultures. If sufficient amniotic fluid could not be obtained or if the patient's temperature was above 38° C, an abdominal amniocentesis was performed.

When the tocolysis score[1] was 5 or less, attempts were made to inhibit labor with either: (1) a 9.5% alcohol infusion (7.5 ml/kg/hr for 2 hours, 1.5 ml/kg/hr for 10 hours) or (2) terbutaline (250 μg subcutaneously 4 to 6 hours, followed by 5 mg orally three times per day).

All patients are given a broad-spectrum antibiotic (ampicillin, cephalosporin) even if afebrile with membranes intact. Dexamethasone (12 mg intramuscularly every 12 hours, two times) was given if it appeared that delivery could be delayed for at least 24 hours. A L/S ratio was then obtained 24 hours after the last steroid injection.

A cesarean section was recommended if the fetus was in other than a vertex presentation. In two cases the cesarean section was done with the fetus in the vertex presentation solely because of inevitable premature delivery. The classical cesarean section (vertical) technique included at least a partial development of a bladder flap.

Informed consent was obtained from each woman and her husband concerning our protocols, and they were required to sign an authorization for experimental use of drugs.

From the Department of Obstetrics and Gynecology, University of California, Davis Medical Center.

Presented at the Forty-fifth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Gleneden Beach, Oregon, September 26-30, 1978.

Syphilis	1	1

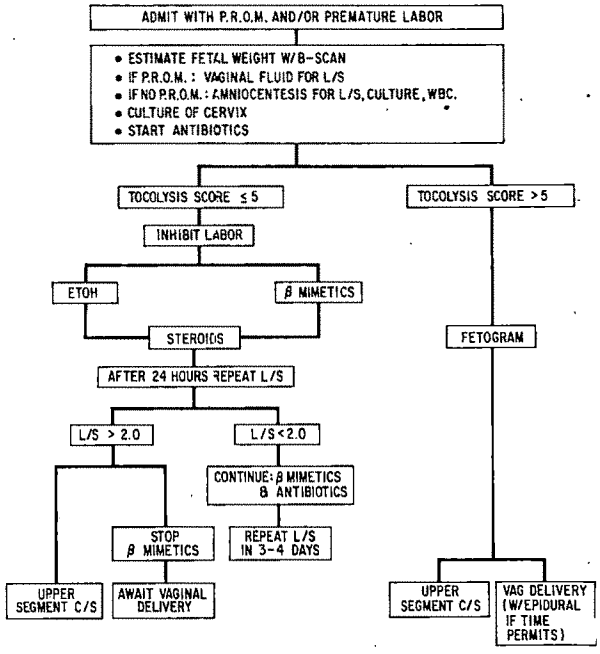

Fig. 1. Protocol for delivery of very premature infant.

Results

Twenty-two of the patients arrived in the hospital in late labor, and nothing more than delivery could be accomplished. The survival rate of the neonates in this group was 66%. After excluding patients who refused to give consent for use of our protocol or who had medical contraindications, efforts were made to inhibit labor in 58 women. In eight of these 58 patients, the decision was reversed because of suspected abruptio placentae, congenital anomalies, or revision of fetal weight estimation to more or less than the original. Admission diagnoses are listed in Table I. All 10 of the patients with severe toxemia had their pregnancies terminated by cesarean section. All of the cases of abruptio placentae were Stage 0 (i.e., no need for transfusion and no sign of fetal distress), the diagnosis being made after the delivery in five of the eight cases.

Of the 26 cesarean sections that were performed, seven were in the lower uterine segment, and 19 were in the upper segment (with four sets of twins). Twenty-seven of these 30 infants were viable, but only 23 survived. The lower uterine–segment cesarean section elicited a survival rate of only 43%. If the two fetuses with Potter's syndrome and the one stillborn infant with a prolapsed cord are excluded, the survival of the viable-size infants from the upper-segment operation is 95% (Table II) ($p < 0.05$). The mean gestational age for those delivered by cesarean section was 29.2 weeks as compared with that of the total group of 29.8 weeks. In Table II survival is analyzed according to mode of delivery. In Table III the indications for cesarean section are listed.

Seventy-two of the fetuses were delivered vaginally, including 10 of those in breech presentation, and the survival rate was 61%. The subsequent intraventricular hemorrhage rate among these newborn infants delivered vaginally was 21%, and of these only 20% survived (Table IV). The incidence of subsequent intraventricular hemorrhage was nearly twice as high in those infants delivered by low forceps as in those delivered by any other technique. One stillborn fetus had an intraventricular hemorrhage. Among the 30 fetuses delivered by cesarean section there were three intraventricular hemorrhages. Of all the neonatal deaths, 44% were associated with intraventricular hemorrhage.

Table V shows a 24% incidence of congenital anomalies. Six of these infants were delivered by cesarean section (Table V). Among the neonatal complications (Table VI), five infants had septicemia, only one of whose mother had received antibiotics prior to delivery. Infants born to mothers receiving antibiotics had a survival rate of 83%, while those not receiving antibiotics had a survival rate of 47% ($p < 0.03$).

There were only 18 newborn infants (Table VII) who had received the entire steroid protocol while in utero. Of these, 17 survived (94%) as compared with a 60% survival rate in those who had not received the entire protocol ($p < 0.10$). Of those newborn infants developing respiratory distress syndrome (RDS), the survival rate was higher when they were delivered by classical cesarean section (91%) as compared with those who had been delivered vaginally (33%).

The overall survival rate for all newborn infants weighing 800 to 1,350 grams was 65%. Postpartum maternal complications were essentially nil. Among those who had cesarean sections, three mothers were febrile without any other serious sequelae. Those mothers

with severe toxemia recovered rapidly. In one case of a woman undergoing a low transverse cesarean section for a small premature infant in a breech presentation, the cervix was lacerated as the infant was lifted from deep in the pelvis through the abdominal incision.

The following cases are presented to illustrate the problems of intrauterine infection and estimation of length of gestation in these women.

Case reports

Case 1. A 33-year-old infertility patient, para 0-1-0-0, whose membranes ruptured at the twenty-eighth week of gestation, was hospitalized elsewhere for 10 days, then transferred to UCD Medical Center because of a fever to 39° C. She was admitted to our hospital afebrile with normal laboratory findings and no labor. The estimated fetal weight was 1,100 grams, and fetal activity and a nonstress fetal heart rate test were normal. An amniocentesis recovered scant amounts of fluid which showed a white blood cell count of 4+ but no bacteria. Estriol (E_3) and human placental lactogen (hPL) levels were within normal limits.

The patient left the hospital against medical advice, but continued with broad-spectrum antibiotic therapy. Four days after leaving the hospital, she reported to her local practitioner that fetal movements had markedly decreased, but since a normal fetal heart rate was heard, she was reassured. The next day, fetal heart tones could not be heard, and she was subsequently delivered vaginally of a 1,510 gram stillborn infant from which pseudomonas was cultured.

Case 2. A 28-year-old woman, para 2-0-1-2, with a prior cesarean section for fetal macrosomia experienced rupture of the membranes at 26 weeks' gestation with the estimated fetal weight being 600 grams. The patient was placed on the protocol of steroids and antibiotics, but labor did not ensue and the patient was discharged home after a hospital stay of 6 days.

At 28 weeks, the patient was still afebrile, but the white blood cell count had risen to 23,000/cu mm. An amniocentesis demonstrated a white blood cell count of 4+ (and subsequently *Hemophilus vaginalis* was cultured). One gram of ampicillin was infused into the amniotic cavity prior to delivery. An 830 gram female infant in an incomplete breech presentation was subsequently delivered by classical cesarean section in good condition.

Although the newborn trachea and gastric fluid both showed a 4+ white blood cell count and bacteria on the smear, the cultures were negative. The mother and the infant were treated with prophylactic antibiotics and both did well.

Case 3. A 19-year-old woman, para 0-0-0-0 was referred to UCD Medical Center with a hisory of silent labor at 30 weeks' gestation. Upon admission, the cervix was 5 to 6 cm dilated, and membranes were bulging. Uterine activity was minimal and ultrasonic scan agreed with the estimated fetal age. After 3 days of bed rest, the cervix appeared to be only 2 to 3 cm dilated, and the membranes had receded. The fetal heart rate and E_3 and hPL levels were within normal limits.

An attempt at a Wurm procedure was made, but after the placement of sutures, clear amniotic fluid began to leak through the cervix. The sutures were removed, and she was continued on a regimen of ampicillin as immediate delivery was anticipated.

However, no further progress in cervical dilatation was noted over the next 15 days. Daily white blood cell counts were obtained and nonstress fetal heart rate tests were performed twice weekly. Without any changes in the white blood cell count or temperature, active labor began and she was quickly delivered of a 1,810 gram female infant in poor condition. The infant was found to have Klebsiella pneumonia and required 17 weeks of intensive care for chronic lung disease. The same Klebsiella organism was cultured post partum from the maternal cervix and uterine cavity.

Comment

Our experience suggests that the major obstetric problems surrounding the delivery of the tiny prema-

ture newborn infant remain largely unsolved. The ultimate solution lies in the prevention of premature labor. If this cannot be done, then the major obstetric goal becomes the delivery of the tiny infant in optimal condition for subsequent development. There are several ways of solving these problems. The obstetric literature suggests that various premature labor–inhibition protocols are successful, but nearly all deal with cases of tocolysis scores lower than those described here.[3, 4]

Reports from some clinics suggest that in the absence of ruptured membranes, between 75% and 80% of the diagnoses of premature labor, in retrospect, were incorrect—the patients were not in premature labor. Others suggest that the error is as low as 30%.[4, 5] The problem of diagnosing premature labor is illustrated by Kubli's statement that in West Germany 1 million ampules and 6 million tablets of ritodrine are used annually in the prevention of premature labor in a country in which only 600,000 newborn infants are delivered per year.[4]

In this study, although only a minority of the tiny infants received the complete protocol, the data suggest that its basic concepts are valid. The benefits of steroid therapy for fetal lung maturation between 28 and 32 weeks' gestation are now proved.[7] Our prior preliminary study showed that in 20 matched cases the incidence of RDS in newborn infants weighing between 900 and 1,300 grams was reduced from 40% to 10% by the use of steroids ($p < 0.05$). Most of the neonates in the present study were delivered before the 24 hour minimum time after steroid therapy, but those who were delivered after 24 hours apparently benefited.

At the University of California, Davis Medical Center, our success with inhibition of labor is less than that generally reported in the literature[2, 3] and is about equal to that ascribed to bed rest alone. Given that steroid therapy will mature fetal lungs, even a 24 hour delay in delivery could be beneficial; however, there is general agreement that it is undesirable to deliver a tiny infant saturated with any of these tocolytic drugs. Our own lack of precision in determining when to forestall labor is illustrated by our errors in inhibiting labor in cases of unrecognized abruptio placentae or chorioamnionitis or by the opposite error of only observing a pregnant woman while she quietly and unexpectedly is delivered of a 900 gram infant.

The two controversial aspects of our protocol are the routine use of antibiotics and the frequent use of the classical cesarean section. The low-birth weight fetuses

Table VII. Effect of steroid protocol on survival by mode of delivery in 91 infants

tolerate the stress of labor less well than do the mature fetuses,[8] and less is known about the interpretation of fetal heart rate patterns of the tiny premature than about those of the mature fetus. Thus electronic monitoring offers these fetuses even less protection than it does the mature fetuses.[9] We have concluded that the severe abrupt decelerations (variable) of the FHR are often less well tolerated by these small fetuses than by the larger, mature ones.

In the absence of a well-developed lower uterine segment in the woman in premature labor, it is preferable to do a classical cesarean section, even with its immediate and remote increased risks for these patients. There is no logic in performing abdominal delivery to avoid fetal trauma and then encounter a difficult delivery through an inadequate lower-segment incision, which frequently need to be extended into a "T" incision. After nearly 40 years' experience at The Johns Hopkins Hospital, Williams[10] in 1930 recommended that the classical incision was preferred for elective cesarean section or for those women in early labor. The present reluctance to perform classical cesarean section is perhaps exaggerated, although admittedly subsequent rupture of these scars can be a rare disaster.

Steward and associates[11] found that those tiny newborn infants delivered by cesarean section did better than those delivered vaginally. In the present series only one neonate delivered by classical cesarean section died. While the findings are of borderline significance, they suggest that the tiny premature infant delivered by classical cesarean section has a better survival rate with less morbidity than those delivered by a transverse lower-segment uterine incision or vaginally. If cesarean section rates are going to be 20% or more, the small premature infant should surely benefit by this type of atraumatic delivery. This hospital's cesarean section rate of 30% for the tiny premature infant is probably too low.

Our second controversial aspect of therapy is the routine use of antibiotics, even in women with only suspected premature labor. This is based upon the concept that chorioamnionitis can be a relatively silent cause of labor. We have had, during this study, three women with Listeria and two with group B β-streptococcus whose only symptoms were premature labor and fever. In three of the five cases, the maternal fever was less than 38° C. It seems reasonable to assume that chorioamnionitis is the etiology of many cases of premature labor, even in those with intact membranes, and that antibiotics may reduce uterine activity in these circumstances.

Leukocytes in the amniotic fluid may only reflect premature labor, for approximately 20% of the amniotic fluid samples from these patients showed elevated leukocyte counts often without significant bacterial growth. When bacteria are found in amniotic fluid, amniotic cavity lavage with antibiotics is performed, and the fetus is delivered within a few hours.

The disadvantages of treating all cases of premature labor with antibiotics are that it may be a waste of medication or it may cause unnecessary sensitization to the antibiotic. Its use may also confuse bacterial study of the newborn infant. The large, multicenter study[12] frequently cited by those advocating no antibiotics for premature rupture of the membranes involved the use of a broad-spectrum antibiotic which probably did not reach the amniotic cavity in therapeutic quantities.

The case histories suggest the difficulties of preventing intrauterine infection in women with ruptured membranes. Antibiotics were obviously only partially successful, especially when used longer than 4 days, However, of the five neonates developing septicemia, four of the mothers did not receive any antibiotics. In addition to preventing neonatal illness due to susceptible organisms (streptococcus, listeria, etc.), routine antibiotic therapy may protect the newborn infant whose immunity is suppressed by steroid therapy. However, the apparent overall increased newborn survival rate with maternal antibiotic therapy is difficult to evaluate, since there was no effort made to randomize its use.

The occurrence of intraventricular hemorrhage in these small premature infants is perhaps the greatest

tragedy that can occur. The tiny premature infant is especially susceptible to this type of bleeding and its sequelae of hydrocephalus. Methods of prevention are unknown. Since the availability of computerized tomography (CT) scanners, the incidence of intraventricular hemorrhage in these infants has been found to be much higher than previously suspected.[13] Whether delivery by cesarean section will reduce the incidence of this dreadful complication is unknown at the present time. Our one case of fetal intraventricular hemorrhage prior to the onset of labor suggests that no obstetrical technique can completely prevent this newborn complication. Routine CT scanning of all tiny newborn infants may confirm our impression that the incidence of subsequent intraventricular hemorrhage is reduced by abdominal delivery.

A major problem for us has been the diagnosis of fetal anomalies incompatible with life in women in premature labor. In two cases, we antenatally diagnosed Potter's syndrome (renal agenesis) based on fetal growth retardation, absent amniotic fluid, and no urine production. Both fetuses died in utero, and while neither weighed over 1,200 grams, they demonstrated only severe growth retardation and normal genitourinary tracts. On the other hand, we have delivered by cesarean section two tiny newborn infants with Potter's syndrome following premature labor and signs of fetal distress. Increased precision with ultrasonic scanning may increase our ability to accurately diagnose these fetal anomalies.

Many of these women in premature labor must be relatively hemoconcentrated, as four of our patients, after being placed at bed rest and given intravenous fluid, have required 2 to 4 u of packed red cells in order to maintain admission hematocrits (with no clinical or laboratory evidence of blood loss). Attempts to assure normal blood volume expansion during pregnancy may be an important prophylaxis in the prevention of premature labor.

Another neglected aspect of the prevention of premature labor is the assurance of tranquility among pregnant women. Much has been written about the adverse effects of the neonatal intensive care unit on bonding and subsequent maternal-infant relationships. However, the frequent occurrence of inadequate maternal adjustments to pregnancy seen in women delivered prematurely is impressive to those dealing with this group of women. This suggests that an abnormal psychological relationship may begin between the woman and her fetus long before the onset of labor. There is little information on how the obstetrician can bring tranquility to the patient with an unwanted pregnancy, as many times the problems have no apparent practical solution.

It is obvious that the development of class III neonatal intensive care units has been a major contribution in improving the outlook for the tiny newborn infant. A recent estimate of a hospital cost of approximately $100,000 per normal suriviving newborn infant weighing 1,000 grams and less indicates the tremendous amount of expert care that the infant requires.[14] While such cases are relatively rare, obstetrics could make a significant contribution in terms of medical costs if such tiny infants could be delivered in better condition. Although our analysis is of a nonrandomized, relatively small series, it does suggest that the routine use of intrapartum steroid and antibiotic drugs, plus delivery by classical cesarean section, may make a contribution to the ultimate survival of these tiny infants. This is especially so in terms of newborn morbidity.

Discussion

DR. LESTER T. HIBBARD, Los Angeles, California. I have enjoyed reading this thought-provoking presentation of an important clinical problem. A statistical evaluation of the data is difficult to make because premature infants are not a particularly homogenous group. This is because of the large number and variety of complications that are associated with prematurity, such as multiple gestation, obstetic hemorrhage, chorioamnionitis, breech presentation or transverse lie, toxemia, cord accident, and anomalies.

In this paper, the proposition is advanced that the survival and morbidity of infants weighing between 800 and 1,350 grams can be improved by the utilization of tocolytic agents to inhibit labor and by the addition of dexamethasone for lung maturation, prophylactic antibiotics for the prevention of chorioamnionitis, and cesarean section to reduce birth trauma, preferably by a vertical incision extending into the upper uterine segment.

In our experience at Women's Hospital, steroid therapy for lung maturation between 28 and 32 weeks substantially reduces respiratory distress and modestly reduces the perinatal mortality rate. But we still have reservations about steroids because the long-term impact on other organ systems is not known. Witness diethylstilbestrol.

We also find that chorioamnionitis is a constant problem in the management of prematurity, particularly when premature rupture of the membranes is followed by a long latent period prior to labor. Whether or not antibiotics should be used routinely is still debatable. One of the problems is to obtain precise bacteriologic information so as to be in a position to select an appropriate antibiotic. We have found that cervical cultures provide little useful information unless certain pathogens, such as gonococci or *Listeria monocytogenes,* are identified. Transabdominal cultures are more helpful, but the organisms recovered are not always the pathogens responsible for the infection. And there are hazards in the indiscriminate use of antibiotics as is illustrated by two of the authors' case examples of antibiotic therapy where an apparent superinfection resulted from the overgrowth of resistant microorganisms. One infant was stillborn with a pseudomonal infection and the other contracted disabling Klebsiella pneumonia. Our philosophy has been to treat only the obvious cases of chorioamnionitis and to withhold antibiotics in doubtful cases on the theory that the newborn infant will be better served by the ability of our neonatologists to obtain meaningful cultures prior to the initiation of therapy.

I believe that the most valuable part of the paper presented is the recommendation that abdominal delivery be employed more often and that the operation be performed in such a manner as to eliminate unnecessary operation trauma to the fetus. The key to successful management of the tiny premature infant is to ensure that the infant is born in good condition. It has been our experience that when the cervix is soft the labor proceeds rapidly without electronic or biochemical evidence of fetal distress and vaginal delivery utilizing a generous episiotomy will be sufficient. The importance of a nontraumatic vaginal delivery is illustrated by the authors' 28 infants born vaginally shortly after hospital admission of the mother with a quite respectable 66% survival rate. Where cesarean section appears to be most valuable is in those cases where premature labor begins, usually following a period of ruptured membranes, with a firm, posterior, and uneffaced cervix. If progress is slow, or there is evidence of fetal distress, an abdominal delivery greatly improves the chances for the survival of a healthy infant. The liberal utilization of a vertical incision extending as far as necessary into the upper uterine segment is far preferable to an inadequate transverse incision in a small lower uterine segment or a "T" extension of a transverse incision. I suggest that those of you who are concerned with the healing of the upper uterine segment review Potter's[1] technique for surgical repair of classical section incisions published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY more than 20 years ago.

DR. JACK G. HALLATT, Los Angeles, California. We should look at the other side of the coin too. Prematurity and immaturity denote a compromised pregnancy with poor outcome and a high incidence of central nervous system deficit. Dr. Goodlin has suggested that classical cesarean section may improve this outlook; however, we still do not know the true role of method of delivery in the outcome of the immature, premature, compromised pregnancy. Prematurity itself is no threat to the health or welfare of the mother. Cesarean section is not without risk to the mother. There is a tenfold increased incidence of risk to the mother by cesarean section over vaginal delivery. There is another tenfold increased risk of uterine rupture following a classical cesarean section with a subsequent pregnancy.

This morbidity must be taken into consideration in an evaluation of the benefit-risk ratio. Should we risk the health of the mother for the possible improved salvage of this unknown quantity, the immature, premature infant? I am not quite convinced.

DR. THEODORE W. LORING, Eureka, California. I would like to mention an experience of mine which I think fits somewhat into this picture, that of a primagravid patient delivered approximately 2 years ago of a twin pregnancy. Weightwise the infants fit into Dr. Goodlin's group. However, they were born with cardiac problems and respiratory problems. They remained in our intensive care unit in Eureka for approximately 24 hours and were then transferred to Children's Hospital, in Oakland, to the intensive care unit. They remained in Oakland for approximately 3 months. Recently I was appointed to the Blue Shield Board of Directors and the Medical Director of the Board said, "You're one of those guys who has been spending our dollars on premature babies." I then looked into the matter of what happened to these two infants and found out that Blue Shield had expended approximately $225,000 in the care of these infants. Roughly $55,000 of that amount was spent on blood gas determinations. The babies are back in Eureka now; they had some atrial-septal defects and had open-heart surgery. They really are not active, healthy babies and perhaps never will be. The mother and father are deathly afraid of ever having another child. I wonder if in a situation of this nature we are doing a little bit more than necessary in attempting to save these infants who not too long ago perhaps would have died. Maybe these infants are intended to die. There was an article in the *Journal of Pediatrics* sometime ago wherein it was stated that the cost of taking care of a small premature infant to the time the baby goes home averages $200,000. I wonder, Dr. Goodlin, if you have any figures on the long-term survival and condition of these infants. You mentioned that one child is going to school and doing well. I wonder if we have any long-term figures to prove that we are doing something worthwhile.

DR. BRUCE B. ROLF, Los Angeles, California. The best way to deal with the tiny infant is to delay or prevent premature labor and birth. We must reach more of the indigent patients who account for many of the premature births. I wish to comment on extra care for the average normal patient who may also have premature labor. A pelvic examination to evaluate the cervix for early effacement at every prenatal visit may anticipate the risk of early labor. In our study, detection of effacement was treated first by insertion of a Smith-Hodge pessary and restriction of physical and sexual activity. If cervical dilatation was observed at weekly follow-up, a nylon Shirodkar cerclage and bed rest regimen as late as 28 weeks sometimes gained another 4 to 8 weeks. Barter has recommended extended bed rest after early detection of multiple pregnancy for reduction of premature births. It has been my observation that the bicornuate uterus behaves with the same relative cervical insufficiency as does multiple pregnancy. When we reviewed our cases of late cervical insufficiency, we found that a considerable number were former infertility patients who had shown an arcuate uterus on prior hysterosalpingogram. It is important for the gynecologist to review the x-ray films for configuration of the uterus as well as for tubal status. Ranney has reported on the familial trait of rapid early labors. This group also deserves frequent evaluation of the cervix for early effacement in the hope that premature labor may be delayed.

DR. RAYMOND J. JENNETT, Phoenix, Arizona. The authors have pointed out that intraventricular hemorrhage is the main threat to these tiny newborn infants. I think it should also be pointed out that Leviton and Gilles, in reviewing the collaborative project data, have shown that germinal matrix hemorrhage, a major threat to these babies, in turn is the precursor to fatal intraventricular hemorrhage, and some of the few risk factors they could identify in association with germinal matrix hemorrhage were cesarean section and hyaline membrane disease. This, in turn, should lead us back to Dr. Kimball's paper pointing out the relationship between endorphin and prolactin elaboration and the role this may have on the observed good effect of labor in the reduction of hyaline membrane disease in premature infants. Although in our department we are also aggressively following the authors' approach, that is, delivering these babies by cesarean section, we are coming up with the grim possibility that our results may not be what we had anticipated. When the outcome of these infants is compared to that of babies born in small hospitals and transported in, the latter appear to do better. This may again relate back to the matter presented in Dr. Kimball's paper. It should also stimulate Dr. Kimball to continue to gather "hard data" on this important subject.

DR. GOODLIN (Closing). It would indeed be better to have a larger sample size, but not many institutions have a large volume of tiny newborn infants. Of necessity, the study should be of short duration, for in the 25 months required to accumulate these 100 cases our techniques with ultrasound and amniotic fluid assessment improved markedly, while a preference for conduction-type anesthesia for cesarean sections has evolved and is a possible detriment.

I believe that the obstetric management of these fetuses demands as much skill as any problem that we face. It is often difficult to diagnose the presence of amnionitis, abruptio placentae, fetal anomalies, and so forth. Another concept that I have tried to "sell" is that we should abandon the technique of watchful waiting, particularly with the very tiny premature infant. A decision should probably be made either to perform a late abortion (infanticide?) or to turn to classical cesarean section when delivery seems inevitable. The condition

of many of these tiny newborn infants after vaginal delivery, if allowed to occur, is so bad that the survivors are usually afflicted with severe central nervous system problems.

In partial rebuttal to Dr. Hibbard's statement, the State Board of Health's figures for his hospital suggests that their present techniques are not optimal for normal survival of these tiny newborn infants. These figures may not be precise, but every obstetrician needs to observe the children from the intensive care nursery. I have been shocked at how badly many of the surviving tiny infants from our own unit have done.

In speaking to Dr. Hallatt's comments, I will say that we are all concerned with maternal welfare and the risk of classical cesarean section in these patients. I would suggest, however, that the occurrence of severe central nervous system problems among their children should cause us to re-evaluate the theoretical risk of cesarean section for the mothers versus the real risk of central nervous system problems in their children.

In partial answer to Dr. Loring, I was referring to the data from New Zealand which suggest that children born to mothers given steroids are doing as well in school as those who were not treated. As you know, the overall survival and performance of these children born prematurely are not as good as those of term infants. Until society accepts infanticide, we can only do our best for these tiny newborn infants to assure their optimal survival.

In answer to Dr. Jennett, I was not aware that cesarean section increased the rate of intraventricular hemorrhage in these tiny infants. My understanding was that the Arizona data suggested that it did not decrease the incidence. Only when we have a large series of these tiny infants delivered alternately by classical cesarean section versus vaginal delivery and studied by the CT scanner will we know the answer to this question. Neonatal factors seem much more important in the development of intraventricular hemorrhage, and the importance of obstetric factors may not be demonstrated unless the series is especially large.

The audience has shown skepticism in accepting the conclusion of this study, which admittedly has statistical defects. However, until a larger, better study is performed, I suggest that the present data are sufficient to begin programs of more active intervention for delivery of these tiny infants. Since their occurrence fortunately is rare, such a concept should not appreciably increase overall cesarean section rates. In the same manner that we no longer accept procrastination in prolonged labor, I believe we should not procrastinate when delivery seems inevitable for these tiny infants.

Addendum

Recently, two gravid women receiving our premature labor protocol developed apparent pulmonary edema. Extensive clinical studies suggested the cause was acute hypervolemia from mobilization of extracellular fluids (as shown by 30% decreases in hemoglobin values) plus the terbutaline therapy.

Squamous carcinoma of the vulva: Results of treatment, 1938 to 1976

J. L. BENEDET, M.D.
M. TURKO, M.D.
R. N. FAIREY, M.D.
D. A. BOYES, M.D.
Vancouver, British Columbia, Canada

Clinical data on 264 patients with squamous cell carcinoma of the vulva seen between 1938 and 1976 are reported. Two hundred and four patients were "eligible" for 5 year assessment for a 55% survival rate. Patients treated with radical vulvectomy and bilateral lymphadenectomy had a corrected 5 year survival rate of 86% if the lymph nodes failed to show metastatic disease. Twenty-eight percent of the patients treated with lymphadenectomy had lymph node metastasis at the time of surgery. The presence of lymphatic metastasis appeared to be the most significant prognostic factor. The results obtained have led to a degree of individualization in current treatment policies, together with a re-evaluation of the possible role of radiotherapy. (AM. J. OBSTET. GYNECOL. 134:201, 1979.)

CARCINOMA OF THE VULVA is the least common of the major gynecologic malignancies, ranking a distant fourth behind cancer of the cervix, ovary, and endometrium, and currently accounts for approximately 4% of all gynecologic cancers. At present, a combination of radical vulvectomy and bilateral inguinal-femoral lymphadenectomy is most often recommended[1-3] as the treatment method of choice for invasive carcinoma of the vulva. Many of the patients with this disorder are elderly and in poor medical condition, which may make selection of this treatment modality difficult and, at times, unwise.

The purpose of this paper is to review the experience obtained in the treatment of squamous carcinoma of the vulva by a variety of methods as employed at the Cancer Control Agency of British Columbia and the Vancouver General Hospital for the period 1938 to 1976 and to indicate how this experience has led to a greater degree of individualization in current treatment policies.

From the Cancer Control Agency of British Columbia and the Department of Obstetrics and Gynaecology, Faculty of Medicine, University of British Columbia.

Presented at the Forty-fifth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Gleneden Beach, Oregon, September 26-30, 1978.

Material and methods

The Cancer Control Agency of British Columbia (CCABC) and its predecessor, the British Columbia Cancer Institute (BCCI), is the major referral and treatment center for gynecologic cancer in the province of British Columbia. Although treatment policies and referral patterns have changed over the 38 years covered by this study, at present virtually all of the invasive cancers of the vulva seen in the province of British Columbia are referred to the Agency for evaluation and treatment. In the early years of the study, the initial surgical treatment was often carried out in the patient's community and patients were only referred to the Institute when recurrence or persistence of disease occurred. Although we employ radical vulvectomy and bilateral inguinal-femoral lymphadenectomy as the mainstay of treatment for squamous carcinoma of the vulva, currently we are also using combination radiotherapy and surgery for the treatment of perineal lesions involving the anal sphincter. Also, in certain instances where the patient's general medical condition was such that they were felt to be unsuitable for complete surgery, radical vulvectomy alone was done in many instances.

The charts of all patients referred to the CCABC or to the Vancouver General Hospital with the diagnosis of carcinoma of the vulva were reviewed. Patients referred with the diagnosis of melanoma, sarcoma, adenocarcinoma, or in situ carcinoma involving the vulva

were excluded from this particular study. During the interval 1938 to 1976, 264 patients were referred with a diagnosis of invasive squamous cell carcinoma.

Sixty of the 264 patients are within 5 years of follow-up and these cases were not used to compute survival statistics but were included in the assessment of presenting complaints, location of lesions, and complications.

Results

Table I shows the age distribution of the 264 patients. The youngest patient seen was 28 years of age with the oldest being 93 years. It is apparent that the disease is one of the elderly woman with disease occurring most commonly in the eighth decade (i.e., 70 to 79 years). Seventy-three percent of the patients seen were 60 years of age or older.

The presenting symptoms for the entire series are listed in Table II. A mass or lesion and pruritus noted by the patient were the two most common complaints. Pain or irritation occurred in 24% of patients, with bleeding or discharge in only 6% of individuals.

The location of the various lesions is shown in Table III. As expected, most lesions occurred on either the labia majora or the labia minora. Fifteen percent of the patients had lesions which were thought to be predominantly clitoral in origin. In 11.4%, the lesion was extensive, occupying the entire vulva, and the site of origin could not be determined. There were a further 18 patients in whom the exact site could not be determined because of insufficient data in the records.

Table IV presents the treatment method versus the stage of disease. All cases were retrospectively staged using the TNM staging system of the International Federation of Gynecology and Obstetrics. A total of 204 patients were eligible for 5 year assessment and their treatment methods, together with stage, are presented in Table V. Sixty-nine patients were treated with radical vulvectomy and superficial node dissection, superficial node dissection referring to bilateral inguinal-femoral lymphadenectomy. A further 51 patients had radical vulvectomy together with superficial and deep node dissection, deep node dissection referring to bilateral pelvic lymphadenectomy. Forty-two patients were treated with vulvectomy or wide local excision and 22 patients received radiotherapy as the only method of treatment. Five patients had radical vulvectomy in combination with an exenteration-type procedure for disease affecting the anus or bladder, as well as the vulva. Of this group, three were posterior and two were anterior exenterations.

A further seven patients were treated with a combination of surgery and various forms of radiotherapy as planned definitive treatment. This modality was used for cases where the disease was initially inoperable in an attempt to make it operable or where postoperatively disease was beyond the surgical margins. The numbers are small but the results are encouraging as five of the seven patients were alive and well at 5 years.

In eight patients, no treatment was given due to general medical condition of the individual or the patient's refusal to undergo therapy. One hundred forty-four patients had either Stage I or Stage II disease. There were seven patients in whom the data were insufficient to permit accurate staging.

Table VI presents the treatment method versus outcome for the 204 patients who were eligible for 5 year assessment. Approximately 77% of the patients treated

with radical vulvectomy and bilateral inguinal-femoral node dissection were alive and well with no evidence of disease at 5 years. Those individuals in whom bilateral pelvic lymphadenectomy was done in addition to radical vulvectomy and superficial node dissection had a 69% 5 year survival rate. Over all, 55% of the patients were alive and free of disease at 5 years, irrespective of stage or treatment method.

The relationship of nodal involvement at the time of radical surgery to outcome is presented in Table VII. Patients who had only removal of inguinal-femoral nodes and in whom the nodes were negative had a corrected 5 year survival rate of 86%. In those individuals with positive superficial nodes, the survival rate decreased to 56%.

In patients who were treated with radical vulvectomy and inguinal-femoral and bilateral pelvic lymphadenectomy, the overall 5 year survival rate was approximately 69%. No patients were seen in whom the deep nodes were positive and the superficial nodes were negative. If all nodes were negative or if only the superficial nodes were involved, the survival data are similar to those for patients with negative inguinal-femoral nodes without pelvic lymphadenectomy. Two of four patients with pelvic disease were alive and well at 5 years. No patient with a lesion less than 2.5 cm in greatest diameter had nodal disease. The four patients with positive pelvic nodes were individuals with either clitoral lesions or extensive lesions involving the entire vulva. Twenty-five percent of the patients had bilateral nodal disease. In all, 34 (28%) of the patients who had node dissection had positive nodes at the time of surgery. This figure is low in comparison to those of other series[1, 2] in the literature and may be a reflection of inadequate histologic study of the material or earlier diagnosis and treatment as 99 of 120 patients who had node dissections had either Stage I or Stage II disease.

The overall 5 year survival results by stage are presented in Table VIII. The crude 5 year survival result for all stages was approximately 55% and when corrected for death due to other causes was 58.2%. The corrected 5 year survival rates for Stage I and II disease were 85% and 58%, respectively. Although the numbers are small, the corresponding corrected 5 year survival rate for Stage III disease was 24%.

There were 163 patients available for 10 year

follow-up and their results by stage are presented in Table IX. The figures in parentheses are the corresponding results for this group of patients at 5 years. In comparing the two sets of figures, it is interesting to note that very few patients died of disease beyond 5 years. However, the number of patients dying of intercurrent disease increased markedly after 5 years, as expected when one is dealing with a group of predominantly older individuals.

Table X presents the data on 20 of the 44 patients treated by vulvectomy or wide local excision. An argument is often made that patients with vulvar carcinoma, because of their relatively advanced age, should not be subjected to major radical surgical procedures as their anticipated life span is probably short. As can be seen, a significant number of patients of advanced age went on to die of intercurrent disease, in many instances 10 years or more following a diagnosis of their disorder. Analysis of these cases also indicated that in certain individuals, because of the early stage of disease, together with the particular growth characteristics of the tumor, procedures other than radical vulvectomy and lymphadenectomy may be effective in achieving control and possibly cure of disease.

Table XI presents the complications for the patients in this series. The overall complication rate was 22.4%. Six patients had more than one complication and there were two postoperative deaths in this series (0.8%). As expected, the most common postoperative complications were problems with wound healing or necrosis. Bilateral lymphedema of the lower extremities was the next most common complication. Of those patients with wound necrosis, six required additional surgical management of this complication; three underwent skin grafting and a further three had debridement and resuturing of wounds postoperatively.

Comment

Results of this study confirm the work of others[1–3] in that carcinoma of the vulva is an uncommon gynecologic malignancy occurring most often in women in the older age group. There is little doubt that radical vulvectomy and bilateral inguinal-femoral lymphadenectomy appears to be the method producing the best results in terms of survival and cure of disease of patients in this series. At present, this is our treatment method of choice in suitable individuals. The combination of radical vulvectomy and bilateral inguinal-femoral lymphadenectomy is perhaps the best cancer operation in the armamentarium of the gynecologic oncologist as it embodies all of the basic principles of a good cancer operation, i.e., en bloc resection of the primary tumor site, together with its primary lymph node drainage areas. As has been shown many times, squamous carcinoma of the vulva is a tumor which spreads predominantly by direct extension and by the lymphatics.[4–6] It has little propensity for blood-borne metastases. Nevertheless, it is our responsibility to constantly

evaluate our results to see if less radical methods of treatment produce acceptable results. As was shown earlier in this study, a significant number of patients treated with what today would be considered inadequate therapy, i.e., vulvectomy alone, did survive for a significant period of time without apparent recurrence of disease. The argument as to whether or not lymphadenectomy should be done has been widely debated,[1-6] with most authorities feeling that it is of definite value. What is still controversial, however, is the routine use of pelvic lymphadenectomy. Between the years 1955 and 1965, we routinely performed pelvic lymphadenectomy as an integral part of operation in all patients with vulvar carcinoma. As indicated earlier, only four of 51 patients had positive pelvic node disease. These findings have influenced us in abandoning the routine use of pelvic lymphadenectomy and reserving it for those cases in which positive inguinal-femoral nodes are found at the time of surgery or if the

lesion is clitoral in origin. We believe that, with the above exceptions, the infrequent occurrence of involved pelvic nodes in early stages of disease does not justify the potentially increased surgical morbidity.

What is needed is a better method of identifying those patients who require pelvic lymphadenectomy so that better individualization of treatment can be made. Clinical assessment of lymph node involvement preoperatively has shown error rates ranging from 13% to 39%.[2, 7]

It behooves us to constantly seek better and less traumatic methods for the treatment of this disorder. For these reasons, we are currently evaluating the use of radiotherapy to convert inoperable lesions to operable ones and also in lesions located in the area of the posterior fourchette which were previously treated with radical vulvectomy and an exenteration-type procedure. There is little doubt that radical vulvectomy and lymphadenectomy are disfiguring procedures and can produce serious sexual and marital dysfunction, particularly in the younger patients. For these reasons, we are also evaluating the possible role of megavoltage irradiation to enable us to be less radical with our surgery. Detailed analysis concerning the radiotherapy methods and results at our center is the subject of another report currently under preparation.

Finally, our experience indicates that a degree of individualization in the treatment of squamous carcinoma of the vulva can be achieved with acceptable results.

Discussion

Dr. Wilson Footer, Oakland, California. Individualization of treatment is the key phrase in discussions of carcinoma of the vulva today. No one wants to come out and say that the classical routine treatment consisting of radical vulvectomy and en bloc dissection of the superficial and deep inguinal-femoral nodes and the pelvic nodes should be abandoned. For the woman with spread of vulvar malignancy to the inguinal and iliac nodes, and no further, it is the ideal treatment. But to subject every patient to that routine has indicated a nonanalytic approach.

I abandoned the shield incision in 1942 when I had such an incision break down. Since then I have performed the vulvectomy separately and then proceeded to the groin dissection on the side of the tumor and in many instances the opposite side because of central location of the primary or because positive nodes were found on the first side. When inguinal nodes were positive, if the patient's general condition permitted, deep inguinal and pelvic node dissections were performed. No patients, other than those with melanomas, have had recurrences in the tissue between the inguinal and vulvar incisions. In 1975, Ballon and Lamb recommended this use of separate vulvar and inguinal incisions and found no increase in tumor recurrence.

The authors stated that no patient with a lesion less than 2.5 cm in greatest diameter had nodal disease. I wish we could rely upon size alone, but we cannot. Figge found that 10% of lesions less than 2 cm had nodal involvement. Others have quoted various percentages of patients with lesions less than 1 cm who had positive nodes. I operated upon one patient with a lesion slightly more than 1 cm who had one positive node in the femoral canal. Size of the primary tumor can not be relied upon to decide to forego groin dissection.

Ideally treatment should be individualized. Wide excision of the lesion and a separate incision for the groin dissection on that side are the minimum that should be considered in the otherwise healthy patients. Then, if positive nodes are encountered, deep inguinal and pelvic lymphadenectomies are done and the step approach is carried out on the opposite side. That is, if the inguinal nodes are negative, the pelvic lymphadenectomy is not done; if positive, it is done.

It has been recommended that lesions involving the clitoris require pelvic lymphadenectomy even if the inguinal nodes are negative because of direct lymphatic spread bypassing the inguinal nodes. The experience of Way tends to negate this recommendation. In 1977, Piver and Xynos came to the same conclusion as Way and stated that the surgical treatment of carcinoma of the clitoris does not differ from that of other locations of carcinoma of the vulva.

Such modalities as radiation to the nodal areas, local applications of 5-fluorouracil, systemic chemotherapy, cryosurgery, and laser therapy should be thought of if only to be discarded as inappropriate for the individual patient. Finally there are some patients who are better off if no treatment is undertaken.

Reconstructive surgery has a definite place for certain women either as a modification of the repair of the original vulvectomy or as a secondary procedure.

Dr. Turko (Closing). I believe one key to the man-

agement of this disease is to consider a more flexible approach. Over the past 25 years we have been impressed that this may be appropriate in lesions involving the posterior fourchette and encroaching on the anal sphincter. Traditionally the rectum has been sacrificed in such instances but we now have seven cases treated by preoperative radiation to this area, followed by a radical vulvectomy and node dissection. In these cases the surgical specimen has revealed no residual disease in the perineal area. In January, I had the pleasure of appearing on a panel with Mr. Stanley Way and we discussed this concept. Mr. Way feels very strongly that surgery is the tnly method of treatment for vulvar carcinoma but he also indicated that in the future he might well consider preoperative irradiation in some instances. We have also recently begun to use postoperative megavoltage irradiation to the pelvis in cases that have proved to have unsuspected positive inguinal nodes and where a deep node dissection was not performed. Our early results are quite encouraging.

When one reviews the literature one sometimes encounters the statement that deep node dissections are associated with no increased morbidity or increased operative time. One can only wonder at the type of deep node dissection that is being carried out in such instances. The description in one paper suggests a digital dissection through the fossa ovalis. It has been our feeling that if a deep node dissection is performed it must involve a wide exposure extraperitoneally with a thorough dissection to the level of the common iliac bifurcation.

The value of intravenous urography prior to abdominal hysterectomy for gynecologic disease

ROBERT A. SACK, M.D.
Whittier, California

Negligence and failure to "test timely" are the two most common charges in obstetric and gynecologic malpractice suits. Both charges are often made in cases involving urinary tract injury during gynecologic surgery. These injuries occur most commonly during abdominal hysterectomy. This report is a 6 year study of 170 consecutive abdominal hysterectomies to ascertain the value of routine preoperative urography in preventing urinary tract injuries. As a control, 260 consecutive abdominal hysterectomies were performed without preoperative urography. There was one ureteral transection in the control group, but unrecognized urinary tract injuries did not occur in either the study or control group. The risks, costs, and benefits of urography are analyzed. (AM. J. OBSTET. GYNECOL. 134:208, 1979.)

A RECENT REVIEW of 1,852 malpractice suits against physicians noted negligence and failure to "test timely" as the two most common charges in these cases.[1] Injuries to the urinary tract during pelvic operations frequently result in a charge of negligence against the operating surgeon. In gynecology, these injuries occur most commonly during abdominal hysterectomy.[2]

A survey of local attorneys who are called upon to defend surgeons in negligence cases involving urinary tract injuries reveals they are often faced with the added charge of failure to "test timely." A plaintiff's attorney in these cases has little difficulty in locating expert witnesses willing to testify that a preoperative intravenous urogram might have prevented the injury.

That such testimony can be readily obtained is not surprising. The intimate embryologic and functional association of the genital and urologic systems is well recognized.[3] Intravenous urography is well established in gynecology as a prerequisite in the staging of invasive cervical carcinoma.[4] It is also a useful diagnostic procedure for the detection of recurrent carcinoma of the cervix.[5]

Two articles have appeared in the world medical literature recommending routine preoperative urography for all patients scheduled to undergo major gynecologic operations.[6, 7] Both of these articles cite the detection of unsuspected renal and extrarenal pathology as the reason for this recommendation.

The purpose of this 6 year study of 430 consecutive abdominal hysterectomies for gynecologic disease was to ascertain the value of preoperative urography in preventing urinary tract injury.

Material and methods

Making available or denying a potentially beneficial preoperative diagnostic test in order to conduct a prospective study presents both an ethical dilemma and a medicolegal hazard. In this study the ethical dilemma was solved by matching surgeons rather than patients.

The subject group of 170 patients were all operated upon by one surgeon during the 6 year period January 1, 1972, through December 31, 1977. All of these patients underwent intravenous urography on the day prior to scheduled abdominal hysterectomy. This routine screening procedure was an established part of the surgeon's preoperative workup and was not a deviation from his customary practice.

During the same 6 year period, the 260 patients in the control group were all operated upon by a second surgeon. None of these patients underwent preoperative intravenous urography. Again this was not a deviation from this surgeon's usual routine.

Both surgeons are Board certified and of the same age. They are products of the same medical college, internship, and residency training program. Both have practiced independently of each other in the same community for 20 years and admit all of their patients to the same hospital. Neither surgeon performs so-

called prophylactic or elective hysterectomy. In other words, no operations in either series were performed for uterine cancer prophylaxis, contraception, or menstrual inconvenience.

Both ovaries were removed in more than 80% of the 430 patients. There was a final diagnosis of malignancy in 107 (25%) of the cases.

The average age in the subject group was 47.1 years; in the control group it was 46.9 years. The youngest patient in either series was 26; the oldest was 78. Both of these patients were in the control group and were operated upon for adenocarcinoma of the endometrium.

There were 1,893 abdominal hysterectomies in the hospital during the same 6 year period. The average age of all patients undergoing abdominal hysterectomy was 44.1 years.

Surgical technique. Both surgeons employ the same techniques with respect to verifying the location of the ureters. In all cases, the ureters are identified at the pelvic brim, and their location on the floor of the pelvis is determined by visualization and/or palpation.

In cases in which there is anatomic distortion due to the disease process, the ureters are dissected out before the hysterectomy is performed. In some cases with extensive pelvic floor disease, this dissection is not always feasible. In these cases, or in any case in which the possibility of ureteral or bladder injury exists, the following routine is carried out. At the completion of the operation, but before abdominal closure, the anesthesiologist intravenously injects 5 cc of indigo carmine. While this is being done, the circulating nurse distends the urinary bladder with normal saline instilled through the indwelling catheter. A cystotomy is performed in the distended urinary bladder. It can then be verified under direct vision that dye-stained urine is being ejected through both ureteral orifices. If the ureters are intact, the bladder and abdominal wall are closed. Intravenous indigo carmine and cystotomy produced no complication in any patient.

Results

No urinary tract injuries occurred in the study group of 170 patients in whom preoperative intravenous urography was done. The preoperative studies did demonstrate a 2.9% incidence of congenital anomalies. There were four instances of ureteral duplication and one renal agenesis. No other significant renal or extrarenal pathology was demonstrated. There were 17 (10%) minor reactions to the intravenous contrast agent, but no severe or fetal reactions occurred.

There was one ureteral transection in the control group. This injury occurred in a 73-year-old patient during the debulking of a Stage III serous cystadenocarcinoma of the ovary. The injury was recognized immediately and repaired; it healed without sequelae. This patient died of ovarian disease 3 years after operation and subsequent chemotherapy.

There was one case of carcinoma of the left kidney in the control group. This was in a 52-year-old patient being operated upon for atypical adenomatous hyperplasia of the endometrium. The asymptomatic carcinoma of the kidney was discovered during routine intra-abdominal exploration at the time of the hysterectomy. She is alive and well 2 years after irradiation and left radical nephrectomy.

There were only two intravenous urographic studies done in the control group of 260 patients, and these were done postoperatively on the two patients noted above.

Comment

Before any procedure becomes established as a routine in medical or surgical practice, the risk/benefit and cost/benefit ratios must be evaluated.

There are two risks associated with intravenous urography: reaction to the contrast agent and radiation exposure. Although no patient in this small series experienced a severe or fatal reaction to the intravenous injection of the contrast agent, tragic results have been reported. A review of 318,500 examinations using contrast media revealed a severe reaction in 1:14,000, and death in 1:40,000.[8] Of special interest to physicians caring for an aging population, this same study noted a marked increase in severe and fatal reactions in patients aged 50 or older.

The second risk concerns the long-term effects of the radiation received at the time of the x-ray study. This risk is impossible to evaluate, but it has been shown that four 14 by 17 inch x-ray views at 110 kV(p), 7.2 mamp 40 inch target skin distance produces 0.107 rads internally.[9]

The cost of routine preoperative intravenous urograms can be readily calculated. There were 1,893 abdominal hysterectomies in the hospital during the 6 years of this study. If the test has been routinely performed on each patient, at $100 per examination, the cost would have been $189,300. If the 1,893 patients had all been admitted to the hospital one day early, in order to perform the study, the cost would soar to over $400,000.

It is revealing to project these cost figures nationally for the same 6 year period as in the present study. Hysterectomy is the most frequent major operation performed in the United States, and as far back as 1973, 688,000 hysterectomies were performed.[10] This

number was also noted to be increasing, so a yearly average of 700,000 for the 6 years of this study would be conservative. This translates into 4,200,000 hysterectomies during the 6 year period January 1, 1972, through December 31, 1977. Using $100 as the cost for each examination, this results in a 6 year cost for this one diagnostic study of $420 million. If these patients had been admitted one day early and had postoperative intravenous urography also been done, the total 6 year cost would approximate $1,500,000,000.

There appear to be three benefits that might derive from preoperative intravenous urograms. These are defense against malpractice suits, the demonstration of unsuspected renal or extrarenal pathology, and prevention of urinary tract injury at the time of operation.

The first of these possible benefits is to the physician and not to the patient. In the medicolegal climate in which medicine operates today, it has become commonplace to order multiple tests that might be of value as a defense in malpractice suits.[1] Using preoperative and/or postoperative intravenous urograms solely as a defense against the charge of failure to "test timely" seems impossible to justify in the face of the risks and costs involved. Futhermore, it has been shown that physicians cannot find protection by ordering a battery of tests for the purpose of avoiding malpractice suits.[1]

That preoperative intravenous urograms can, and do, demonstrate previously unsuspected renal and extrarenal pathology is undeniable. It is also undeniable that careful abdominal exploration at the time of surgery has similar capabilities. Exploration has two distinct advantages: there is no cost and virtually no added risk.

It might be argued that the conventional intravenous urographic study has the capability of evaluating renal function, but this is not the case. Reports have shown that excretory urograms are not capable of quantitating the functional status of the kidney.[11] The ordinary intravenous urographic study simply depicts the structure of the urinary collecting system.

With respect to the test's benefit in preventing injury at the time of surgery, no urinary tract injuries occurred in the study group, while there was a ureteral injury in the control group.

At first glance, these results might seem to indicate a positive value for preoperative intravenous urograms. On closer analysis, this is not the case. In the control group where the ureteral transection occurred, the ureter was in its normal anatomic position. This injury was due to surgical error and not the lack of a preoperative x-ray examination.

This study, of an admittedly small group of patients, has failed to produce evidence that preoperative intravenous urograms are of value in preventing urinary tract injury at the time of abdominal hysterectomy.

The study does not conclude that preoperative intravenous urograms are never indicated in gynecologic surgery. It only questions their routine usage. This procedure, as well as a myriad of others, should only be prudently and selectively utilized.

A recent report states that most members of the medical profession are fiduciary failures.[12] Whether or not we physicians accept this, society is holding us increasingly responsible for both the physical and financial health of the patients we serve.

I wish to acknowledge the contributions of Thomas Murrieta, M.D. He made available the patients in the study group and also made valuable suggestions as to the final form of this report.

Discussion

DR. CHARLES E. WEBER, La Jolla, California. Let us examine the two problems that Dr. Sack has defined in his straightforward, uncomplicated paper, void of graphs, tables, figures, and similar soporific material. The first is risk-to-benefit balance. It cannot be denied that a certain amount of risk is associated with the procedure. Dr. Sack has referred to the collective data of Ansell,[1] reflecting the incidence of reaction as 1 in 2,000 (mild), 1 in 14,000 (severe), and 1 in 40,000 (death). The deaths are seemingly age related, probably a function of myocardial susceptibility. Certainly, careful pretest screening for history of allergy or sensitivity together with selective pre-examination testing will eliminate the majority of reactions. Familiarity with reactions and prompt attention to treatment by the personnel involved with the testing can decrease the seriousness of the reactions which do occur. Dr. Sack presented no reactions in his series, and the data at Scripps Hospital in La Jolla are similar to those reported by Ansell,[1] although we have had no fatalities.

The benefits derived from intravenous pyelography can be broken down into two categories. The first is the detection of unsuspected urinary tract pathology, including congenital anomalies, pre-existing disease, and anatomic distortion associated with pelvic pathology; additionally, there is the detection of extrarenal pathology; additionally, there is the detection of extrarenal pathology. Dr. Sack referred to the data of Roden and colleagues, reflecting 22% unsuspected significant renal anomalies and 6.4% noteworthy extrarenal abnormalities. This represents six times the yield produced with routine chest film survey (4.6%).

I will, with your permission, resort to anecdotal data at this time. Mrs. M was admitted to Scripps Hospital for pelvic surgery because of uterine prolapse and pelvic floor relaxation; additionally, she had a large incarcerated umbilical hernia. Rather than the proposed surgery, the patient had resection of a parathyroid adenoma. The routine preoperative urogram revealed left renal and ureteral lithiasis. In the course of evaluation for this problem, serum calcium levels were obtained and reported as 11.1 (normal 8.4 to 10.6). The diagnosis of parathyroid adenoma then became quite simple and was proved in surgical specimen. Currently, she has been relieved of not only the parathyroid tumor but also the stones and, more recently, the prolapsed uterus and incarcerated unbilical hernia for which she originally sought help.

A 40-year old patient was admitted for hysterectomy because of uncontrollable menometrorrhagia and adenomyosis. The routine preoperative urogram demonstrated an unsuspected, nonfunctioning right kidney. After urologic evaluation, the proposed surgery was successfully carried out much to the relief of the physician and the satisfaction of the patient and her attorney husband.

And a patient was scheduled for anticipated pelvic surgery because of a right adnexal mass associated with an intrauterine contraceptive device and felt to be a unilateral pelvic abscess. Routine pyelography was done prior to the surgery, and Grade III hydroureter and hydronephrosis secondary to blockage of the ureter at the ureteropelvic junction from the pelvic mass were detected. The patient had the surgery. The urinary abnormality is slowly returning to normal.

I leave the implications of postoperative pyelography in these patients without prior knowledge of their preexisting urinary system abnormalities to your imagination and speculation. While these cases are certainly not commonplace occurrences and do represent anecdotal data, they are factual.

The second aspect of value of this procedure alludes to the operative benefits or prevention of urinary tract injuries during surgery because of the knowledge gained by intravenous pyelography. I agree wholeheartedly with Dr. Sack in his assertion that skillful surgical management of the procedure is the most important element in preventing any urologic complications. Pelvic, including urologic, anatomy must be thoroughly defined at surgery and careful attention must be paid to any suspected urologic injury. In this regard, the technique of operative intravenous urography has been refined by my associate, Charles F. Wright, M.D.,* and the radiology staff at Scripps Memorial Hospital in La Jolla. This has given us a simple, effective method for detecting suspected urinary tract injuries during surgery. Time does not allow my detailing the procedure, but it is well worth your attention.

Finally, is routine intravenous pyelography cost effective? To the individual patient with positive or negative findings and/or benefit from the procedure, the answer is a simple "yes or no." Obviously, the $400,000 to which Dr. Sack alludes could have been spent more effectively in other ways, so the overall answer is more evasive. But compare, if you will, the cost effectiveness of a simple test in daily use, a total of 4 million tests a year at a cost of approximately $80 million a year to detect 450 patients with positive and treatable disease at a cost of approximately $160,000 a case.[3] I refer, of course, to routine, mandated premarital serology. I am forced to provide the latter by mandate, but I shall continue to provide the former by choice.

*Unpublished data.

DR. THEODORE W. LORING, Eureka, California. Initially, when I read the summary of Dr. Sack's paper, I felt he was going to end up recommending that we routinely use intravenous pyelography. However, I was very happy in reading the full manuscript to find out that he does not so recommend. Although he did have one transected ureter in the group, he pointed out that the intravenous pyelogram did not prevent this and would not have prevented it. I would like to take this opportunity to give you a bit of privileged information with regard to urinary tract injuries. I think that urinary tract injuries occur much more often then we realize. I serve as a director of Norcal Mutual Insurance Company and also have the privilege of being the obstetrics-gynecology reviewer of all claims that come into our office. Norcal Mutual represents approximately 5,200 physicians in northern California, excluding the Bay Area. Between the date of the formation of our company on November 1, 1975, to August 23, 1978, we had 1,248 claims or incidences, including suits, reported to the company. The claims involving our specialty amount to 228 cases of 19.1% of the total. Of these 228, 89 involve obstetrics, which is 39% of the obstetrics-gynecology claims or 7.5% of all claims the company has received. In gynecology we have had 139 claims—this is 61% of the claims involving obstetrics-gynecology or 11.2% of the total claims of the company. The gynecology group is somewhat alarming in that there were 23 cases involving urinary tract injuries, which is about 16.5% of all our obstetrics-gynecology claims. There is another factor that we must look at in time. We have 29 cases involving laparoscopic tubal sterilizations, 16.5% of all our gynecology claims. I would be the first to agree that these figures are relatively "green." Just what this will cost the company in time, no one can say. Many of them probably will not end up as suits. But at least some costs will be generated to the company. I hope in the future, as our material ages, that I will be able to present to you a more detailed report of where our specialty in with regard to malpractice. I am sure that all of the doctor-owned companies in California, in general, probably will have somewhat the same experience that the Norcal Mutual Company has had. For years I have felt, and I have argued the point, that gynecologists and obstetricians are unfairly rated by being put in a class always above general surgeons. I no longer feel that way.

DR, ROGER W. HOAG, Berkeley, California. The discussion of this paper reminds me of a case which happened in southern Alameda County, in which a woman's abdomen was being explored for a pelvic mass. The surgeon proudly removed this retroperitoneal mass and sent it up to the pathologist, who proceeded to slice it up before he sent back down a report—this was a horseshoe kidney. The surgeon had successfully removed the woman's only kidney. His operative note indicated he had felt her kidneys on manual exploration. She was transferred to Stanford Medical Center for dialysis in the hope of a renal transplant. But none was forthcoming and she died. Needless to say, the case was settled quickly. It seems to me that pyelography might have prevented this accident. I do not speak for routine pyelography. I would be opposed to it. But I think that any gynecologist embarking on a pelvic exploration or anything that might even remotely be a retroperitoneal mass should consider a pelvic kidney or horseshoe kidney and consider the advisability of preoperative urography.

DR. BRUCE B. ROLF, Los Angeles, California. Intravenous pyelography is not an innocuous procedure. The question is whether the added cost of this does warrant its routine use prior to simple hysterectomy. In my own practice, I have experienced one fatality and one near fatality due to anaphylaxis in diagnostic intravenous pyelography. I do believe that there is a place for preoperative intravenous pyelography prior to surgery for adnexal masses. In some instances ureteral catheters should be placed if difficult dissection due to previous pelvic inflammatory disease or postoperative adhesions is anticipated. The urologists in our community in the event of ureteral ligation lament that a pyelogram was not obtained previously. In performing pyelography, it is appropriate that a physician be present either to inject the dye or to take care of possible anaphylactic reaction.

DR. RALPH H. WALKER, North Hollywood, California. Several years ago, when Dr. Dick Simmons was in Los Angeles, he made the remark that most of the cases referred to the Mayo Clinic for ureteral repair after damage were of ureters that were not in the normal location, which had been cut for that reason. In our own care, if there is any adnexal disease that seems to involve the ureter, we utilize ureteral catheters prior to surgery. In those patients who have been operated upon previously and have a large enterocele or vaginal prolapse requiring vaginal plastic repair, we routinely place ureteral catheters prior to surgery and it is amazing in our findings that many of those ureters are not in average or "normal" anatomic locations.

DR. SACK (Closing). What I am going to say may not be fair, but it is also apropos of what we talked about—the malpractice situation and the situations we are encountering, but I am almost afraid that we have changed the old axiom from "physician heal thyself" to "physician treat thyself."

Office termination of pregnancy by "menstrual aspiration"

RALPH W. HALE, M.D.
THOMAS Y. KOBARA, M.D.
SANTOSH D. SHARMA, M.D.
JULIA J. TSUEI, M.D.
EDWIN P. GRAMLICH, M.D.
ROY T. NAKAYAMA, M.D.
Honolulu, Hawaii

A program of office menstrual aspiration was initiated in our institution in 1972. Since that time 1,443 patients have been admitted into the study. These patients were evaluated by age, marital status, gravidity, repeat pregnancy terminations, complications, and detailed tissue analysis as well as contraception utilized at the time of conception and following counseling after the procedure. A majority of these patients were less than 25 years old and single; 28% had had a previous termination and 51% a previous pregnancy. Pathologic evaluations revealed Arias-Stella reaction in 78%. When these data were compared to those of a similar group of women whose pregnancies were terminated in the hospital by suction curettage, it was found that the office procedure is comparatively safe and should therefore be the therapy of choice. (AM. J. OBSTET. GYNECOL. 134:213, 1979.)

IN AUGUST, 1972, a pilot project for the office termination of pregnancy was initiated in the outpatient department of Kapiolani Hospital. The initial findings for the first 181 cases were presented in 1973[5, 8] and led to the conclusion that this procedure was a safe, effective, low-cost method for the termination of early pregnancy. As a result, the study was enlarged and the office procedure compared to the standard hospital suction curettage. An additional 1,262 patients have been admitted to the study since that time for a total of 1,443 patients who have been evaluated.

Material and methods

All of the patients in this study were sexually active and were self-or-physician referred because of delayed menses with or without a positive pregnancy test. Each patient was seen initially by our nurse-practitioner and asked to complete a health questionnaire. The patient then received a detailed explanation of the procedure utilizing audiotapes, pictures, and verbal clarifications. All questions were answered and the patient was then asked to sign an informed consent.

Next a pelvic examination was performed and uterine size was determined. Patients who were estimated to be 8 weeks gestation or less from the day of the last normal menstrual period were admitted to this study and had a blood type and Rh determination. Those who were estimated to be 9 weeks or beyond were scheduled for a hospital suction curettage with general anesthesia.

The menstrual aspiration procedure was preceded by gentle cleansing of the vagina with a povidone-iodine* solution. This was followed by a paracervical block utilizing a total of 16 cc of 1% lidocaine, 4 cc at 3, 5, 7, and 9 o'clock. After satisfactory anesthesia was obtained (at approximately 5 minutes), the anterior lip of the cervix was grasped with an atraumatic tenaculum. With a "no-touch"[7] technique, a 5 mm sterile catheter was then inserted and suction induced with a 50 cc Karmann-type syringe. In some instances, a 6 mm catheter and, on a few occasions, a 7 mm catheter were utilized. All tissue and fluids removed were

carefully measured and sent to our pathologist for evaluation. The patient remained at rest in the examination room for at least 30 minutes following completion of the procedure before she was allowed to leave. All patients were instructed in daily temperature recordings. If the patient was Rh negative, she was routinely given an injection of Rhogam.* The patient was specifically instructed to return or call immediately if any complication arose. A routine follow-up visit was made and a pregnancy test was performed 2 weeks after the procedure.

In an attempt to compare the results obtained by the office procedure with those of in-hospital abortions, we instituted a prospective study of 400 in-hospital abortions which were 8 weeks' gestation or less, and additionally we reviewed the statistics obtained for all hospital abortions in Hawaii over a 4 year period by the Hawaii Pregnancy, Birth Control and Abortion Study. We were unable to obtain the same detailed information for these two studies that we did for the office procedure since most patients had only a brief history related to the procedure.

Results

A total of 1,443 patients had a termination of pregnancy by office suction curettage between August 30, 1972, and May 1, 1977.

In our series, 69% of the patients were less than 25 years of age while 7.7% were 31 or older (Fig. 1). When marital status was considered, 73.5% were single, 16% married, and the remainder widowed, divorced, or separated. A majority (56%) of our patients had no previous pregnancies (Fig. 2) while 25 had five or more. In addition, 22% had a previous abortion and 11% a previous menstrual aspiration.

An assessment of the contraceptive method utilized at the time of conception was made as well as the method preferred following counseling and at the 14 day follow-up visit (Fig. 3). At the time of conception, 44.5% reported they were not utilizing any form of contraception, 4.8% were using an oral contraceptive, 2.5% an intrauterine contraceptive device, 7% a diaphragm, and 17% condoms; two patients reported a failure using the Encare Oval,* and the remainder had used a combination of foam, jelly, withdrawal, and rhythm. Following the procedure and our counseling session, 52% of the patients elected to use oral contraceptives, 14% the IUD, and 10% a diaphragm. The remainder chose some other method. It was interesting that 9.7% chose no contraception and 2% chose abstinence, while 1.5% selected a sterilization procedure.

At the 2 week visit, 49.4% were using or planned to use oral contraceptives, 11.6% the IUD, 9.9% the diaphragm, 10.3% the condom, and the remainder some other form or no contraception. There was an 86% compliance to the 2 week follow-up office visit.

During the procedure, a measurement of the amount of aspirated contents was obtained. In 2% of the cases, aspirated material had a volume of over 100 cc. The maximum volume obtained was 535 cc of blood in one patient. This was retrospectively determined to be at 10 weeks' gestation. A total of 9.5% had 50 to 100 cc of fluid while the remainder had less than 50 cc, 20% having volumes between 30 and 50 cc and 68% having less than 30 cc.

Thirty-two patients (2.2%) had a repeat menstrual

*Rhogam, Ortho Pharm. Corp., Raritan, New Jersey.

*Encare Oval, Eaton-Merz Laboratories, Inc., Norwich, New York.

aspiration for initial failure to abort the pregnancy; two patients (0.1%) had two repeat procedures.

Immediate side effects occurred in only 6% of the patients. The major complaints were nausea and/or vomiting (2.1%) and vertigo and/or syncope (1.6%). Two patients (0.1%) had severe hemorrhage, one requiring an emergency suction curettage. Seven patients (4.8%) reported severe pain. There was one lidocaine reaction (0.06%) and one patient (0.06%) had a stenotic cervix that prevented insertion of the catheter. Additional problems occurred during the 14 day interval prior to re-examination in 13% of the patients. The most frequent complaints were prolonged or heavy bleeding (5%), prolonged or severe cramps (4%), and vaginal discharge (1.5%). Four patients (0.2%) reported an elevated temperature and eight (0.5%) reported chills. All of these patients were examined by a physician. Nine patients (0.6%) were determined to have incomplete abortions, with subsequent completion by repeat menstrual aspiration, intramuscular prostaglandin, or suction curettage. Three patients (0.2%) were found to have ectopic pregnancies; 15 patients (1%) were diagnosed as having endometritis. The remaining 27 patients (1.8%) were diagnosed as having some other condition, most of which were unrelated to the termination procedure or were of a minor nature requiring no therapy.

All tissue obtained during the procedure was sent for pathologic examination and results were compared with the pregnancy test. An Arias-Stella phenomenon was found in 78% of the tissue samples submitted. Of the remainder, 18% were determined to have been pregnant by other pathologic criteria and 4% were not pregnant. A positive pregnancy test occurred with a negative Arias-Stella phenomenon in only 56 (4.4%) patients.

Our study of 420 in-hospital terminations of pregnancy by suction curettage revealed 19% of patients to be over the age of 30 while 49% were less than 25 years old. In this group, 25% had no prior pregnancies and 44% had a prior abortion.

Side effects were encountered in 19% of the hospitalized patients. The most common problem was nausea and/or vomiting which occurred in 14% of the patients. Included in the remaining 5%, however, were two uterine perforations, a laryngospasm, and a cervical laceration. One of the uterine perforations required a hysterectomy. Three patients (0.7%) had subsequent curettage for heavy vaginal bleeding. No information was obtained on contraceptive usage before or after the procedure in this group.

Data obtained from the Hawaii Pregnancy, Birth Control and Abortion study[5] revealed that 22% of

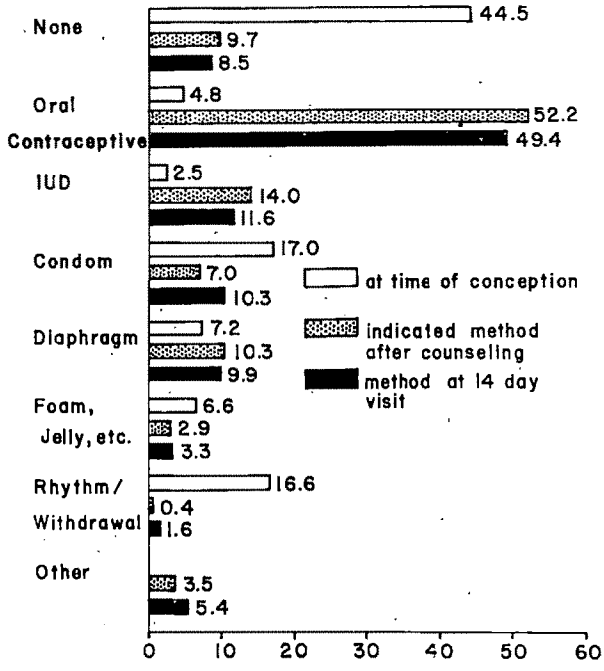

Fig. 3. Contraceptive methods used.

women seeking abortion were less than 20 years old, 34% were between 20 and 24 years old, 21% were between 25 and 29 years old, and 11% were over 30 years of age. It was found that 50.8% had had no previous pregnancies, 27% had two or less, and 22% had more than three. When marital status was considered, 61% had never married. There was a 6.9% complication rate, 75% of which were considered minor. Thirty-four percent of all terminations in this state were at 8 weeks' gestation or less and 31% were at 9 to 10 weeks.

Comment

Early termination of pregnancy is a simple procedure but is not withoout complications. Immediate side effects were experienced by 6% of our patients and by the 2 week visit 13% of the patients had experienced a complication. This rate is higher than that reported in some series[1, 3, 6, 10] but may be due to our detailed reporting and our concern with all effects, whether major or minor.

Of the 32 patients who apparently failed to abort, all had a subsequent procedure and two had the procedure repeated twice. Our failure rate was less than that reported in other series.[2] We believe this low rate was due to careful selection of patients and proficiency and experience gained through repeated procedures. There have been no failures in our last 400 cases.

We compared our percentage rate of side effects with that of the in-hospital abortions and found this prospective study revealed in-hospital abortions to

have a 19% incidence of side effects. The Hawaii[4, 9] study showed a 6.9% incidence of side effects. In both instances, the primary problem appeared to be nausea and/or vomiting which is also seen with the office procedure.

One potential serious complication encountered with the office procedure is excessive hemorrhage. In assessing uterine size, it is possible to misinterpret the history and examination, thereby attempting menstrual aspiration on advanced pregnancies. The one patient in our study who had a severe hemorrhage (over 500 cc) had a more advanced gestation than anticipated. After this incident, we had larger catheters immediately available, as well as oxytocin and intravenous fluids.

Our management of the other common complication, syncope and/or vertigo, has been the use of oxygen. We now keep an oxygen tank available in the office for immediate use.

As noted, the contraceptive practices of our patients were carefully recorded. A number of patients who had repeat menstrual aspirations had been seen by us previously and had been carefully counseled and given a method of contraception. Some of these patients specifically did not use the method for a personal or other reason and again became pregnant. It was also noted that the method selected at the time of the procedure, when motivation is theoretically highest, is frequently not the method that is used or desired 2 weeks later. Our investigations of all cases of repeat menstrual aspiration revealed a method failure in less than 10% of these patients. When contraceptive failures did occur, they were found to be associated with a change in contraceptive method or failure to use any method. It was particularly distressing to observe these repeated undesired pregnancies, since a large proportion of our patients were referred to us from a University student population. We are convinced that adequate counseling and availability of contraceptive methods by themselves will not completely prevent "unwanted" pregnancies.

Detailed histopathologic evaluation was performed on all tissue removed. We initially attempted to correlate the amount of tissue, length of pregnancy, and level of β-subunit of human chorionic gonadotropin but could not find any correlation.[7] In 78% of the patients, an Arias-Stella reaction was reported. This was assumed to be evidence of early pregnancy and after the first 200 cases we began to expect to see this histologic pattern. In those patients who were pregnant but did not have an Arias-Stella reaction, there was marked glandular hyperplasia as has been previously reported.[1] When a positive pregnancy test was obtained and included in the criteria for pregnancy, only 4% of the patients did not show the phenomenon. Two of the three patients with an ectopic pregnancy had the Arias-Stella phenomenon.

A problem which we encountered early in our study and is still unresolved is the appropriate name for this procedure. It has been called "menstrual aspiration," "menstrual regulation,"[3] "menstrual induction,"[8] and "menstrual extraction,"[1] as well as other names.[2] A common acceptable nomenclature such as "uterine aspiration" would assist in popularizing the procedure as well as in collecting complete statistics.

Discussion

Dr. Roger R. Miesfeld, San Diego, California. I also had a problem with the nomenclature a number of years ago until I limited my definition to that proposed by the National Medical Committee of Planned Parenthood in its *Manual of Medical Standards and Guidelines.*[1] They use the term "endometrial aspiration," defined as follows: "Endometrial aspiration for the purpose of early termination of pregnancy is vacuum curettage of the uterus performed within 5 to 14 days after the expected date of menstruation in women in whom it is possible that unplanned, unwanted conception has occurred." This eliminates the term "menstrual" which suggests that menstruation is merely being induced. Menstrual dates are frequently unreliable and therefore I always do a pregnancy test. If

negative, I call it "endometrial aspiration"; if positive, I call it an "abortion." A positive test alerts me that more than 14 days may have passed after menstruation was expected and reminds me of the possibility of ectopic pregnancy, should the aspiration yield very little tissue. Actually I rarely use the term "endometrial aspiration" because we now have available in our laboratory a radioreceptor assay test for human chorionic gonadotropin which we use for patients 1 to 14 days after expected menstruation. This has practically eliminated doing a procedure which has been shown to be unnecessary in as many as 50% of patients since they were in reality not pregnant. Another point that might be made is that the Joint Program for the Study of Abortion,[2] under the auspices of the Center for Disease Control, shows a higher total complication rate for abortions performed at 6 weeks or less than when done at 7 to 8 weeks. Therefore, it might be prudent to wait for a positive urinary chorionic gonadotropin test to lower the complication rate, decrease the number of unnecessary procedures, and decrease the number of failed abortions.

In both the hospital and office groups, the authors' total complication rate is rather high when compared to that in the Center for Disease Control report.[2] However, it appears that these were mainly quite minor complications and I doubt that most of us would have conscientiously reported many of the minimal and minor side effects. It was encouraging to note no major complications in the office group, unless the lidocaine reaction was severe, the patient with 500 cc of blood loss required a transfusion, or the four patients with an elevated temperature showed evidence of a serious infection. In the hospitalized patients, one would expect a high incidence of nausea and vomiting because of the use of general anesthesia. The serious complications of uterine perforation and cervical laceration are also more likely to occur with general anesthesia than with paracervical block. The one major complication, the uterine perforation requiring hysterectomy, is compatible with the major complication rate reported by the Center for Disease Control. I can only surmise that the high total complication rate reflects very conscientious reporting and the low major complication rate indicates a high degree of skill of the operators.

The availability of oxygen and oxytocin was mentioned. I assume the rooms also have an adequate supply of drugs, intravenous solutions, and resuscitative equipment. Preoperative sedation is usually not necessary for the early terminations. However, since I have been using diazepam, 5 to 10 mg intravenously, I have seen a marked decrease in discomfort, and, as has been reported, it helps protect against toxicity by raising the anesthetic seizure threshold. After reading the report of Grimes and associates on five deaths due to paracervical anesthesia used for first-trimester abortion, we now have an emergency "crash cart" in the room whenever we perform an abortion. One point that was not clear to me pertains to the criteria for establishing a diagnosis of pregnancy. The authors reported that 4% were not pregnant. This seems very low when including the 5 and 6 week gestations, unless there were very few in this early group. Also they stated that "in 78% of the patients, an Arias-Stella reaction was reported. This was assumed to be evidence of early pregnancy." Novak[4] stated in *Clinical Obstetrics and Gynecology* that "ASR has been noted after administration of contraceptive pills and clomiphene and occasionally as a physiologic response to the hormones elaborated during a normal cycle. While highly suggestive, it is not pathognomonic of pregnancy." Would Dr. Hale please clarify this point for us?

Since 14% of the patients were lost to follow-up, is it possible that a significant number of complications could have occurred in this group and thus changed the complication rate? Now that you have gained so much experience with early termination, do you plan to do abortions up to 12 weeks as an office procedure?

Finally, although a major medical breakthrough has not been presented, it was reassuring to hear that office abortion carries minimal risk and perhaps has less major complications than do hospital abortions.

DR. HAROLD M. LYONS, Merced, California. There is only one thing that I think we should bear in mind, and that is the problem concerning the Arias-Stella reaction. It is perfectly all right to be partisan about it and to feel strongly that it is useful, or not useful, but do not let anybody write it down, because at the present time medical-legal authorities and malpractice lawyers are having a field day with it. If it appears in a report, it is a presumption of pregnancy which cannot necessarily be proved. If operation is performed for an ectopic pregnancy on the basis of an Arias-Stella phenomenon, and there is no ectopic pregnancy, a suit is likely. We should vocalize this whenever we want, but I think we should keep it out of the written record.

DR. HALE (Closing). Dr. Miesfeld has had a great deal of experience in this area and I was interested to hear what what he said. I will mention one of the problems to be faced in a patient who comes in for "endometrial aspiration." As the length of amenorrhea increases the accuracy of the pregnancy test increases and yet the probability that a patient is pregnant is still only about

94 to 95% even with a positive test. If you look at that another way, the duration of amenorrhea in days, the chance of pregnancy increases almost proportionally to the length of time the patient is amenorrheic. I think that is interesting information to us, because that is why we have determined we would not use the Planned Parenthood definition of endometrial aspiration. We wait now for a positive pregnancy test or until we are absolutely certain in our own minds that pregnancy has taken place. We also do not use the term "endometrial aspiration" because insurance carriers get that confused with endometrial biopsy. I do agree with you that hopefully we can come up with a standard definition. I believe our complication rate is higher because we were looking for complications. We specifically asked patients questions such as: "Did you hurt?" "Did you have bleeding?" "Did you have this or that?" because we wanted to overload our statistics in the realm of what might have been the ultimate, or the maximum number, as opposed to just what patients reported to us. To answer the other questions, the lidocaine reaction was very minor. No patient required transfusion. I was very interested in the comment about preoperative diazepam and think perhaps that might be something we should consider because these patients are highly apprehensive. We do use diazepam in our patients who are going in for hospital abortions and we find that it does reduce anxiety. In terms of the question asked about the diagnosis of pregnancy and the Arias-Stella phenomenon, I want to point out that we had this in 78% of patients; in those who did not have this we used another way in which we could assess pregnancy. This was by either an extreme hypersecretory pattern or test of the beta subunit of human chorionic gonadotropin. Since this last test is not something I would recommend every individual in private practice order, because of the cost, we are comfortable just in looking for abnormal findings. Dr. Lyons, we are only describing it here for your information. There were few patients in whom pregnanccy could not be determined by the use of histopathologic criteria. We did have 14% lost to follow-up. We made every effort to observe these patients and many who were lost to follow-up were not really lost. The patient just did not come back. We got in touch with the attending physician or we got in touch with a roommate or boyfriend, etc., but not the patient. I do not believe that you can use this kind of follow-up in a statistical analysis because you really did not see the patients and you really did not talk to them. In answer to the question about 12 weeks' gestation, I will simply say that I would not be worried about a patient who lost 500 cc of blood. We do very carefully select these patients and we now also have a suction machine in the office just in case we get into trouble and need it. However, I do believe that one has to be highly selective in terms of any pregnancy beyond 6 weeks that will be terminated in the office.

Pretreatment lymphangiography and operative evaluation in carcinoma of the cervix

LEO D. LAGASSE, M.D.
SAMUEL C. BALLON, M.D.
MICHAEL L. BERMAN, M.D.
WATSON G. WATRING, M.D.
Los Angeles, California

Ninety-five patients with cervical carcinoma who were not candidates for definitive operation underwent initial lymphatic and 24-hour nodal phase lymphangiography and lymphadenectomy prior to radiation therapy. Operation by a transperitoneal or extraperitoneal approach consisted of bilateral pelvic and periaortic lymphadenectomy, exploratory laparotomy, and intraperitoneal biopsies as indicated by the findings. Radiation therapy was modified to include proved sites of metastases. Intestinal injuries followed transperitoneal operation and radiation therapy but were uncommon in patients in whom exploration was done by the extraperitoneal route. Eighteen patients (19%) had unsuspected metastases to common iliac or periaortic lymph nodes identified at operation. The characteristics of the primary tumor and the interpretation of the lymphangiogram provided an inaccurate basis on which to modify treatment. As further studies confirm the risk of disseminated disease in those patients with metastases to common iliac and periaortic lymph nodes, future treatment plans might incorporate adjuvant chemotherapy or immunotherapy in addition to extended-field irradiation. (AM. J. OBSTET. GYNECOL. 134:219, 1979.)

CARCINOMA OF THE CERVIX, if untreated, spreads to involve adjacent tissues and lymphatic metastases to pelvic and periaortic nodes are common. Occasionally, metastases by the hematogenous pathway involve lung, bone, and other distant sites. The currently accepted staging of carcinoma of the cervix is based on a clinical and limited radiographic assessment of the extent of the primary tumor.[1] Spread to adjacent organs is identified by pelvic examination, cystoscopy, intravenous pyelography, sigmoidoscopy, and barium enema. Chest roentgenogram, skeletal survey, and tests of hepatic function aid in the detection of distant metastases. No provision exists to determine the volume of the primary tumor independent of stage and the presence of metastases to the pelvic and periaortic lymph nodes.

This report compares the results obtained by lymphangiography and lymphadenectomy in the pretreatment evaluation of the regional lymph nodes and subsequent modification of therapy in patients with carcinoma of the cervix.

Material and methods

One hundred three patients with carcinoma of the cervix underwent pretreatment operative evaluation which consisted of abdominal exploration and pelvic and periaortic lymphadenectomy. Bipedal lymphangiography was performed in 95 of the 103 patients who comprise the study group. Four of the eight patients excluded from this report refused lymphangiography, in two the lymphatics could not be cannulated, and in two the radiographic study was unsatisfactory.

After identification of the individual lymphatic vessels by the intradermal injection of patent blue violet dye into the first web space, an incision over the dorsum of the foot facilitated their isolation and cannulation. Six millimeters of Ethiodol was infused slowly and initial flow pattern studies and delayed films of opacified lymph nodes were obtained. A filling defect in a node not traversed by lymphatics constituted definite

lymphangiographic evidence of a metastasis. Complete replacement of a lymph node and lymphatic obstruction with or without collateral circulation were viewed as indirect evidence of metastatic spread. In the absence of these findings, the lymphangiogram was classified as negative.

Operative evaluation included a careful exploratory laparotomy with combined abdominal and transvaginal palpation of the primary tumor, intraperitoneal cytologic washings, and indicated biopsies. Early in the series, exploration was performed through a vertical, midline hypogastric incision with node biopsies obtained through incisions in the posterior parietal peritoneum. Unacceptable morbidity when this was combined with radiation therapy resulted in the design of an extraperitoneal approach to these node-bearing tissues. This technique, previously described, utilizes a left-sided J-shaped incision and medial reflection of the peritoneum from the underlying vessels.[2] Lymph nodes obtained from bilateral obturator, hypogastric, external iliac, and common iliac and periaortic regions are submitted for separate pathologic evaluation. The presacral space, easily visualized by the extraperitoneal approach, also is dissected. Postoperative abdominal roentgenograms confirmed the adequacy of resection in each of the node-bearing areas.

Results

The operative approach was transperitoneal in 30 patients and extraperitoneal in 65. Small intestinal injuries occurred from 2 to 17 months following operation and radiation in nine of 30 patients (30%) undergoing exploration by the transperitoneal approach. All required further operative intervention and three died of complications. Small intestinal injury requiring resection was noted in one patient in whom the extraperitoneal approach was utilized. Complications of small bowel function were unrelated to the radiation field employed as only one of these 10 patients received radiation therapy to the periaortic region. No significant difference in blood loss, hospital stay, or interval from operation to initiation of radiation therapy existed. Morbidity from lymphangiography was confined to transient discomfort and sterile inflammation at the site of the incision. Pulmonary insufficiency was not observed.

Operative findings detected disease more advanced than the clinical stage in 32 patients (33.6%). In two patients, disease was less than determined by the clinical stage. Of the 32 patients with more extensive tumor,

one had metastases to the ovary and one, to the omentum. Two had extension to the pelvic side wall not detected on bimanual examination and the remaining 28 had unsuspected metastases to pelvic and/or periaortic lymph nodes. Both patients with less advanced disease had pelvic endometriosis as the basis of the discrepancy.

Because metastases to common iliac and periaortic lymph nodes were used as a basis for modification of radiation therapy, these areas were considered together in evaluating results (Table I). Pelvic lymph node metastases were present in 26 patients (27%), with common iliac and periaortic nodes involved in 18 patients (19%). Only two patients with metastases to the common iliac or periaortic lymph nodes had no metastases to the pelvic nodes.

Radiation therapy was modified on the basis of operative findings in 23 patients (24%). Seventeen of 18 patients with metastases to the common iliac or periaortic lymph nodes had 4,320 to 5,120 rads delivered to the level of the twelfth thoracic vertebral body, as previously described.[3] Six patients with pelvic lymph node metastases had an increase in the external component of radiation therapy.

For purposes of analysis, a lymphangiogram was designated as P negative or positive based on the status of the pelvic lymph nodes and C-A negative or positive following evaluation of the common iliac and periaortic nodes (Fig. 1). Results of the lymphangiogram were then compared with the lymphadenectomy specimens from these areas (Table II). Fifty-two patients in whom the lymphangiogram was P negative/C-A negative had no metastases demonstrated at lymphadenectomy. In five patients pelvic lymph node metastases were identified; five patients had metastases to both pelvic and periaortic nodes, and one patient had a metastasis to a periaortic lymph node. Sixteen patients had a lymphangiogram designated as P positive/C-A negative. Biopsies were in agreement in three patients but revealed no metastases in 10 and disease in both pelvic and periaortic lymph nodes in three patients. Sixteen patients had a lymphangiogram interpreted as P negative or positive/C-A positive and in nine of these lymph node biopsies confirmed disease in this area. In seven patients, however, no periaortic lymph node metastases were demonstrated and five of the seven had negative pelvic lymph nodes as well.

In 64 patients (67%) agreement existed between the two diagnostic approaches. Fifteen patients (16%) had disagreement in the form of a false positive or negative lymphangiogram in the pelvis alone. False negative and false positive results were approximately equal in their distribution among the various clinical stages, with false negative results somewhat more common in the early stages and false positive results more common in women with advanced disease.

Comment

Metastases to the common iliac and periaortic lymph nodes occur frequently in patients with advanced carcinoma of the cervix.[4] Data from this series suggest that these areas are involved in up to 20% of patients with earlier stages of disease as well. Operative evaluation of these lymph nodes by a transperitoneal approach has been associated with unacceptable morbidity when combined with extended-field radiation therapy.[5, 6] Complications presumably relate to radiation of larger volumes of tissue and to loops of small intestine fixed to incisions in the posterior parietal peritoneum. The extraperitoneal approach to pretreatment evaluation permits excellent access to the pelvic and periaortic lymph nodes, avoids the incision of the posterior peritoneum, and has decreased morbidity while eliminating deaths following extended field irradiation.

Operative evaluation allows modification of radiation therapy by an increase in the dose to an involved pelvic side wall or extension of the field to encompass the periaortic lymph nodes. In a few patients, the detection of widespread intra-abdominal disease has directed therapy toward palliation of bleeding and prevention of ascites rather than cure.

Although operation can be performed safely by an extraperitoneal approach, any accurate, noninvasive method of lymph node evaluation would be highly desirable. Comparison of data obtained by lymphangiogram with results of lymph node biopsies in this series suggests that lymphangiography provides an inaccurate basis on which to modify radiation therapy. Seventy-nine patients, comprising 83% of the treatment series, probably would have benefited from conventional radiation therapy in the absence of operative evaluation. In these patients, total agreement between lymphangiography and lymphadenectomy (64 patients) or disagreement only in the interpretation of the pelvic lymph nodes (15 patients) existed. In 17% of patients, however, treatment based on the results of the lymphangiogram would have been inappropriate. Extended-field radiation therapy applied to all patients in whom the lymphangiogram was C-A positive would have resulted in the overtreatment of seven patients. An additional nine patients in whom the lymphangiogram was C-A negative might have been undertreated on the basis of metastases documented in these areas at the time of operative evaluation. Routine irradiation of

the periaortic region in any patient with a lymphangiogram read as P positive or C-A positive would have appropriately treated 12 and overtreated 20 patients.

The presence of metastases in the common iliac or periaortic lymph nodes was unrelated to clinical stage, cell type, or grade of the primary tumor. Review of postoperative subtraction films provided a basis for a possible false positive correlation of the pelvic lymph nodes in two patients but was not responsible for any discrepancy in the common iliac or periaortic region.

No data are presented to support an increase in the survival of patients managed by this approach. Many patients with metastases to the periaortic lymph nodes also have occult spread to distant sites. An analysis of those patients in whom therapy fails suggest that distant disease, alone or in combination with pelvic recurrence, is present in 52% to 75%.[4, 6] Further documentation of this finding would not obviate the need to evaluate the periaortic lymph nodes but might provide a basis for adjuvant chemotherapy or immunotherapy in patients with extensive lymphatic involvement.

We would like to acknowledge the assistance of James D. Collins, M.D., Department of Radiology, University of California, Los Angeles, Center for the Health Sciences, Sally Shaw, M.D., and John Werner, M.D., Department of Radiology, City of Hope National Medical Center, and Terry Chamorro, R.N.

Discussion

Dr. David C. Figge, Seattle, Washington. Our current interest in operative staging of cervical cancer was initially stimulated by Nelson in a presentation of 13 such cases before the Society of Gynecologic Oncologists in 1971. The reported inaccuracy of clinical staging was disturbing and has been confirmed by a number of subsequent reports in our literature and by a groupwide protocol study of the gynecologic oncology group. Dr. Lagasse's interesting paper today adds materially to our knowledge of this controversy.

The concept of pretreatment surgical staging in cervical cancer rests on three assumptions. Traditional clinical staging by comparison must be shown to be inaccurate. Treatment modifications must emerge as a result of the surgical procedure and, finally, improved survival is an ultimate goal. Otherwise the increased expense, extended hospitalization, and personal morbidity for the patient are difficult to justify.

In Dr. Lagasse's material, the surgical findings contradicted the clinical staging in one third of the reported cases. In virtually all these cases the disease was more advanced than clinically suspected. Regardless of assigned clinical stage, there was a relatively constant 20% incidence of involved common iliac or aortic node chains. By general agreement such patients should be treated by extended-field radiation directed to the para-aortic area and conventional treatment regimens would be destined to failure in most of these cases.

Any noninvasive technique yielding the same information as surgical staging would be most attractive. Lymphangiography, particularly as supplemented by percutaneous, transperitoneal, fine-needle aspiration of suspicious or positive nodes has been advanced as an alternative. Our essayist reports agreement between the two approaches in only 67% of cases. In 17%, treatment based on the results of a lymphangiogram alone would have been inappropriate. Metastatic nodal disease of less than 0.5 cm in diameter will seldom be detected by lymphangiogram. There is a rather constant 20% false negative result in this diagnostic approach and nodes must be identified as suspicious before fine-needle aspirates are helpful.

Our experience in a rather limited number of patients subjected to pretreatment extraperitoneal node exploration during the past year provides no disagreement. Our first patient was a native Alaskan with early Stage IIB cervical carcinoma. The lymphangiogram was negative. Multiple positive pelvic and paraaortic nodes were confirmed histologically and a subsequent scalene node biopsy was also positive. Our

experience with the lymphangiogram has been most discouraging.

The evidence to date for increased survival by this approach is less than convincing. Reports of long-term survival of patients with positive para-aortic nodes remain mostly anecdotal. Many such patients indeed probably have coincident pelvic recurrence or distant metastases. Often the poor prognosis may reflect, at least in part, the problem of advanced local disease and an overwhelming tumor burden. The prospect may not be all bleak. An interesting recent retrospective study from the New York Medical College reported a limited group of patients with Stage IIB disease arbitrarily treated by extended-field para-aortic radiation. Survival results in this group were significantly higher than in the comparison group treated by conventional fields. Perhaps, as with lymphoma and Hodgkin's disease, we need better to define the patient who may particularly benefit from the findings at staging operation.

This report convincingly recommends the extraperitoneal approach. It appears to be far safer than conventional laparotomy in avoiding the complications that have been reported following radiation. In our patients we have encountered no postirradiation complications to date with this approach. I wonder if Dr. Lagasse would comment further on his preference for the lateral "J" incision. We have found the conventional high, midline incision quite satisfactory, providing that the inferior rectus sheath above the semilunar line is incised laterally from within on both sides.

Dr. William E. Lucas, San Diego, California. Dr. Lagasse has made a significant contribution to our understanding of several aspects of the pattern of spread and diagnosis of lymph node involvement in cervical cancer. This is in addition to a series of studies from the University of California, Los Angeles, under the aegis of Morton. If I am not mistaken, the current President, Dr. Dignam, was involved in some of the earliest of these studies. This is an innovative approach and the lack of morbidity associated with the extraperitoneal approach is a testimony to the acceptability of the technique in skilled hands. The information relating the results of lymphangiography to surgical findings is of considerable value in helping to settle, in the negative, the argument regarding the value of this diagnostic technique in the evaluation of cervical cancer patients. It is our view that if intraperitoneal disease is present, as established by laparoscopy, then lymph node dissection becomes unnecessary. Our protocol is to perform laparoscopy first and then an extraperitoneal para-aortic node dissection via a right periumbilical incision, if there is no intraperitoneal disease. In 20 patients, so far, 25% have had intraperitoneal disease which is much higher than the incidence reported by Dr. Lagasse. These patients have Stage IIB through Stage IV disease. The reasons for carrying out para-aortic and common iliac node sampling are readily appreciated since we need to segregate those patients who, from the outset, will not be cured by conventional radiation fields, because of lymph node involvement at a higher level. These patients become candidates for extended irradiation fields and/or chemotherapy. At our institution, in collaboration with Byfield and Lacey, we are using a protocol which combines irradiation and chemotherapy in all patients who have disease involving the uterus and intraperitoneal structures or para-aortic lymph nodes.

The reasons for doing a pelvic lymphadenectomy are less clear since all these patients are treated with whole-pelvis irradiation, and the pelvic node findings did not significantly alter the treatment plan in 98 of 104 patients. I do not believe that it will be possible, yet, from the design of this study, to learn whether removal of involved pelvic nodes followed by irradiation improves end results, although, this question very much needs to be answered. The converse seems well established, that pelvic lymphadenectomy subsequent to full irradiation increases only morbidity and not cure rate. It is well known that combinations of irradiation and lymphadenectomy increase the incidence of urologic injury and lymphocysts. I would like to ask Dr. Lagasse if, from this study and his previous research into the role of irradiation in sterilizing pelvic lymph nodes containing metastatic cervical cancer, he can develop data which might help us answer the question of whether or not postlymphadenectomy radiation improves survival.

Dr. Ivan I. Langley, Portland, Oregon. I would like to know the amount or the use of left scalene node biopsy as a part of the staging procedure. We have included this and wonder if he has as well.

Dr. Lagasse (Closing). Dr. Figge referred to Sall's cases of Stage IIB carcinoma of the cervix, all of which were treated with periaortic irradiation without prior node biopsies. The 4,500 rads that he used, in the same dosage that we employ, did not cause added complications in his patients. The only complication in the present series that appeared related to extended-field radiation was gastric bleeding in one patient with previous ulcer history.

I believe that staging studies need to be continued so that we will know which patients have spread of disease. Patients with positive common or aortic nodes are possibly at high risk for distant spread and may be candidates for adjuvant chemotherapy. Dr. Figge mentioned that he has performed extraperitoneal lymphadenectomy through a midline incision by peeling the peritoneum free and dissecting behind it. This is an interesting approach which should allow for adequate exposure of the retroperitoneal space.

In answer to Dr. Lucas' question regarding the adequacy of the intraperitoneal exploration, we make a 15 to 20 cm opening in the peritoneum and do a thorough intra-abdominal examination. Tubes and ovaries can be removed through this incision if required by the

presence of abnormality or disease. It is important to detect intraperitoneal metastases when present, and this can be done prior to node removal using the surgical approach we have described. It is not certain if lymphadenectomy itself is therapeutic in patients who have positive nodes. Perhaps removal of very bulky involved nodes will increase the chance of cure with subsequent radiation.

Scalene lymph node biopsies were not done in this series. Metastases to the scalene node may be another indication of systemic disease like the finding of positive periaortic nodes and might indicate which patients should be treated with adjuvant chemotherapy.

Aberrant portions of the müllerian duct found in an ovary

WILLIAM WOOD RUSSELL
Johns Hopkins Hospital Bulletin, vol. 10, pp. 8-10, 1899

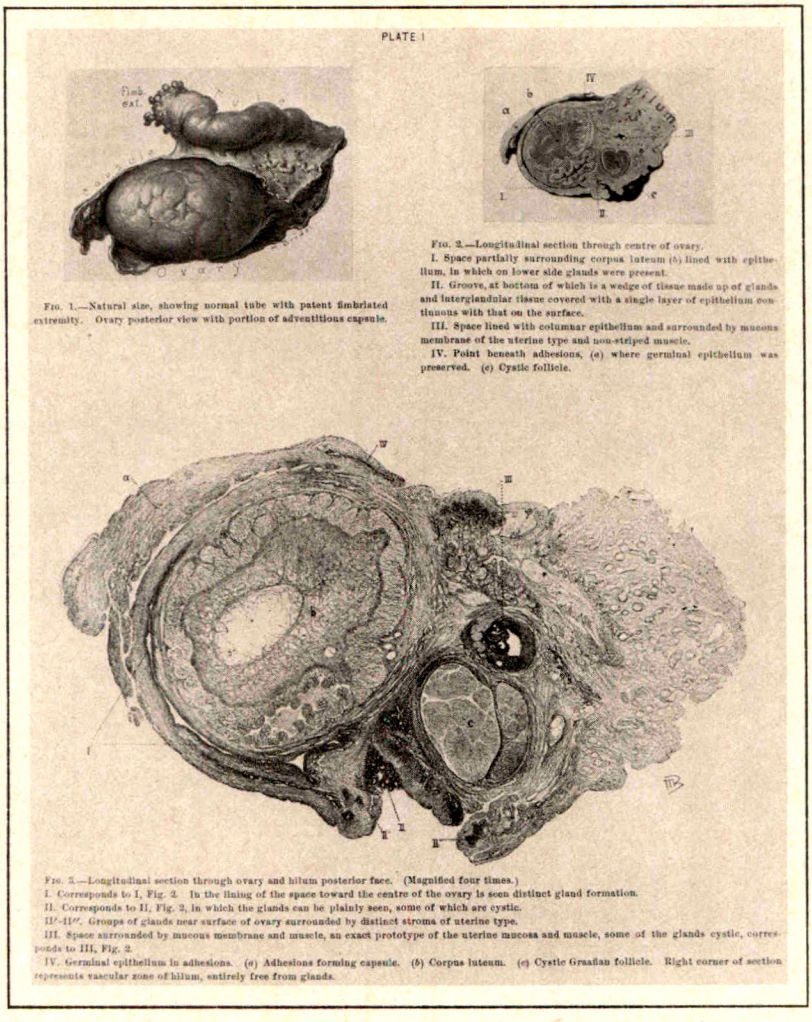

FIG. 1.—Natural size, showing normal tube with patent fimbriated extremity. Ovary posterior view with portion of adventitious capsule.

FIG. 2.—Longitudinal section through centre of ovary.
I. Space partially surrounding corpus luteum (*b*) lined with epithelium, in which on lower side glands were present.
II. Groove, at bottom of which is a wedge of tissue made up of glands and intergiandular tissue covered with a single layer of epithelium continuous with that on the surface.
III. Space lined with columnar epithelium and surrounded by mucous membrane of the uterine type and non-striped muscle.
IV. Point beneath adhesions, (*a*) where germinal epithelium was preserved. (*c*) Cystic follicle.

FIG. 3.—Longitudinal section through ovary and hilum posterior face. (Magnified four times.)
I. Corresponds to I, Fig. 2. In the lining of the space toward the centre of the ovary is seen distinct gland formation.
II. Corresponds to II, Fig. 2, in which the glands can be plainly seen, some of which are cystic.
II′-II″. Groups of glands near surface of ovary surrounded by distinct stroma of uterine type.
III. Space surrounded by mucous membrane and muscle, an exact prototype of the uterine mucosa and muscle, some of the glands cystic, corresponds to III, Fig. 2.
IV. Germinal epithelium in adhesions. (*a*) Adhesions forming capsule. (*b*) Corpus luteum. (*c*) Cystic Graafian follicle. Right corner of section represents vascular zone of hilum, entirely free from glands.

During the latter part of the nineteenth century several writers described pelvic lesions that probably were endometriosis. Carl von Rokitansky may have referred to this entity in his report, "Cystosarcoma adenoides ovarii uterinum" (Lehrb. Pathol. Anat. 3:423, 1861) and Carl Breus used the term "chocolate cyst" in reporting involvement of the uterus and cul-de-sac (Über wahre epithelführende Cystenbildung in Uterus-

0002-9378/79/100225+02$00.20/0 © 1979 The C. V. Mosby Co.

myomen, Leipzig, 1894, F. Deuticke). Russell first reported finding endometrial tissue in the ovaries. Fig. 1 from Plate 1 illustrates the enlarged ovary, while Figs. 2 and 3 demonstrate the foci of endometrial glands and stroma with accompanying smooth muscle. (These figures, incidentally, are from the pen of Max Brödel, the great medical illustrator.) Russell noted: "On microscopic study of the right ovary, we were astonished to find areas which were an exact prototype of the uterine glands and interglandular connective tissue." He described the ovary in detail: "On the posterior surface at a considerable distance from the hilum, was a shallow groove partly filled with glands of the uterine type . . .. In the substance of the ovary . . . was a band of glands imbedded in connective tissue. The glands were arranged as in the normal uterine mucous membrane and opened into the spaces, their epithelium being continuous with its lining membrane. The interglandular connective tissue was composed of small cells with darkly staining oval and round nuclei almost completely filling the cell body, in fact identical with that found in the uterus. Beneath the spaces were bundles of muscle . . .. The whole formed an exact reproduction of a portion of the uterine mucous membrane and muscle." Russell then carefully reviewed the embryology of these tissues and concluded that the aberrant endometrial tissue arose from müllerian duct (paramesonephric) tissue. Robert Meyer argued that metaplasia of celomic membrane gave rise to these lesions (Uber den Stande der Frage der adenomyositis Adenomyome . . ., Zentralbl. Gynaekol. 36:745, 1919). John A. Sampson first coined the term "endometriosis" and explained its histogenesis by "seeding" or implantation from other cysts (Perforating hemorrhagic (chocolate) cysts of the ovary . . ., Arch. Surg. 3:245, 1921). Later Sampson championed the theory of transtubal regurgitation of endometrial fragments during menstruation as the primary cause of this condition (Peritoneal endometriosis, due to menstrual dissemination of endometrial tissue into peritoneal cavity, AM. J. OBSTET. GYNECOL. 14:422, 1927). Russell, with Thomas S. Cullen, a disciple of Howard Kelly, practiced in Baltimore and served as a member of the Department of Gynecology at The Johns Hopkins Hospital. One of the founders of the American College of Surgeons, Russell wrote on many topics of gynecologic interest, including the clinical course of patients with carcinoma of the uterus subsequent to hysterectomy (Johns Hopkins Hosp. Bull. 6:154, 1895) and suprapubic hysterotomy as a means of diagnosis and treatment of diseases of the uterus (Johns Hopkins Hosp. Bull. 17:134, 1906).

COMMUNICATIONS IN BRIEF

This section is suitable for reporting results of therapeutic trials, descriptions of new procedures or instruments, and case reports which illustrate a principle. Reports should be limited to seven hundred words and two references. Use of an illustration or table requires a proportionate reduction in total words.

DURING A RECENT epidemic of Legionnaires' disease which occurred in Vermont between May and October of 1977, 32 confirmed and 24 highly probable cases were studied.[1] The majority of cases occurred in patients with chronic underlying diseases such as cancer or chronic bronchitis, in cigarette smokers, and in the immunocompromised host. One of these patients became ill following a cesarean section.

A 29-year-old woman, gravida 2, para 1, was admitted to a regional hospital on July 26, 1977, because of hypertension related to pregnancy. Her last menstrual period was on December 5, 1976, with an estimated date of confinement of September 11, 1977. Hospitalization became necessary because of increasing blood pressure. During the subsequent week of hospitalization there was a 50% fall in estriols and the patient developed a positive oxytocin challenge test (OCT). Evaluation of gestational age by ultrasound was consistent with the patient's dates. An L/S ratio was less than 1:1. She was transferred on August 2, 1977, to the Maternal Fetal Medicine Service at the Medical Center Hospital of Vermont (MCHV).

The patient's blood pressure was stabilized with intravenous Aldomet and a repeat OCT was scheduled. Prior to the OCT, there was the spontaneous development of profound fetal bradycardia necessitating emergency cesarean section. A 2,120 gram male fetus with Apgar scores of 4 and 6 at 1 and 5 minutes, respectively was born. Forty percent abruptio placentae was present. The patient's first few days of postoperative recovery were without complication.

On postoperative day 4 (day 5 after admission to the MCHV) the patient's temperature was 38° C. On postoperative day 5 the patient complained of sudden onset of sharp, bilateral chest pain and shortness of breath. Because of a previous episode of possible phlebitis in 1970 following an ankle injury, pulmonary embolism was suspected. Arterial blood gases revealed a pH of 7.15, Po_2 of 78, and Pco_2 of 30 on room air. A white blood cell count was 14,700, with a normal differential. The initial chest roentgenogram revealed a prominent heart and congestion. No definite evidence of a pneumonia process or pleural effusion was seen. Roentgenograms obtained approximately 16 hours later revealed increased density in the right and left lower lung fields and the presence of a right pleural effusion. This was suggestive of an inflammatory process. Ventilation-perfusion scan was performed in an attempt to clarify the pulmonary process but did not differentiate a pneumonia process from pulmonary emboli. Temperatures spiked at 38.8° C on postoperative day 5 and 38.5° C on postoperative day 6; still the most likely diagnosis was considered to be pulmonary embolism and the patient was begun on intravenous heparin therapy. Clinical and roentgenographic response was very slow. She was discharged on hospital day 16 to be maintained on oral anticoagulation therapy.

A serum specimen was obtained approximately 3 weeks after discharge for determination of indirect fluorescent antibody against Legionnaires' bacterium and was reported to be 1:512. A single serum of 1:256 or greater is considered significant and makes the diagnosis of Legionnaires' disease highly probable.[1]

Since Legionnaires' disease is known to cause more severe disease in the chronically ill and the immunosuppressed host, it is important to suspect the diagnosis as early as possible so that appropriate antibiotic therapy can be started. It is unknown whether pregnancy, which carries with it an increased risk for viral infections, also carries an increased risk for Legionnaires' disease. The case discussed in this report had a clinical picture compatible with Legionnaires' disease:

sudden onset of undiagnosed pneumonia with granulocytosis, fever, an incubation period of 2 to 10 days, and a pleural effusion. Yet, had there not been a major epidemic of Legionnaires' disease in Vermont and in other states in the northeast at that time, the diagnosis would have been missed. Although it is felt by some that pulmonary embolism is perhaps too often diagnosed and overtreated,[2] our patient did have sudden onset of chest pain with shortness of breath and mild hemoptysis and might well have had both Legionnaires' disease and pulmonary embolism. These latter symptoms have also been described in Legionnaires' disease without evidence of pulmonary embolism, however. In either instance, the addition of erythromycin might have made recovery more rapid.

To our knowledge, this is the first reported association between Legionnaires' disease and pregnancy. The importance and significance of this association is not yet known since total experience with Legionnaires' disease is still very limited. Only an awareness of the possible presence of Legionnaires' disease during pregnancy will lead to an answer to this question as well as to the prompt institution of appropriate therapy.

We thank Dr. Nello Delbel for the referral of this patient.

Prenatal diagnosis of sacrococcygeal teratoma

EDGAR O. HORGER III, M.D.
LINDA M. McCARTER, R.D.M.S.

Departments of Obstetrics and Gynecology and Radiology, Medical University of South Carolina, Charleston, South Carolina

MODERN TECHNIQUES for assessment of fetal malformations include amniocentesis, radiography, amniography, fetography, fetoscopy, and ultrasonography. Perhaps the most valuable and undoubtedly the least hazardous of these techniques is ultrasonography. Hydrocephalus, anencephaly, meningomyelocele, polycystic kidneys, and omphalocele are among the malformations previously diagnosed prenatally by ultrasonography. The following case report documents the prenatal diagnosis of sacrococcygeal teratoma. This diagnosis greatly influenced the subsequent management of the pregnancy.

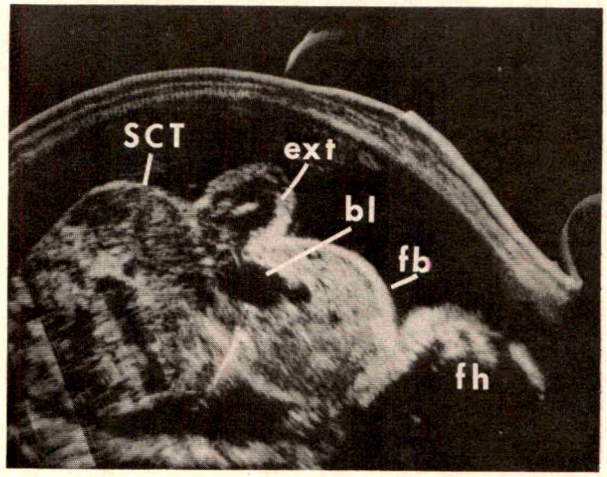

Fig. 1. Ultrasonogram of fetus at 31 weeks' gestation showing large sacrococcygeal teratoma *(SCT). ext,* Lower extremity; *bl,* urinary bladder; *fb,* fetal body; *fh,* fetal head.

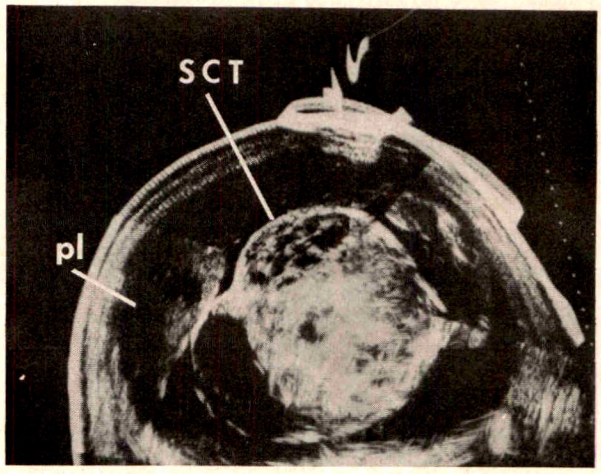

Fig. 2. Ultrasonogram at 31 weeks' gestation showing transverse section through sacrococcygeal teratoma *(SCT).* Bizarre, complex echo pattern with multiple cystic spaces is noted. *pl,* Placenta.

A 29-year-old black woman, gravida 4, para 2, abortus 1, was hospitalized at 31 weeks' gestation because of polyhydramnios and abdominal pain. Her uterine fundal height had increased from 30 to 37 cm during the previous 2 weeks.

Ultrasonography revealed the fetal biparietal diameter and fetal trunk size consistent with 31 weeks' gestation. At the caudal end of the fetal trunk was a complex mass which measured 13 cm in greatest diameter (Figs. 1 and 2). This mass was contiguous with the fetal body. It appeared generally solid, with bizarre internal echoes, but contained multiple cystic areas. No defects were seen in the fetal spine. Distention and subsequent emptying of the fetal urinary bladder were noted. The mass was thought to represent a large sacrococcygeal teratoma. Marked polyhydramnios was present.

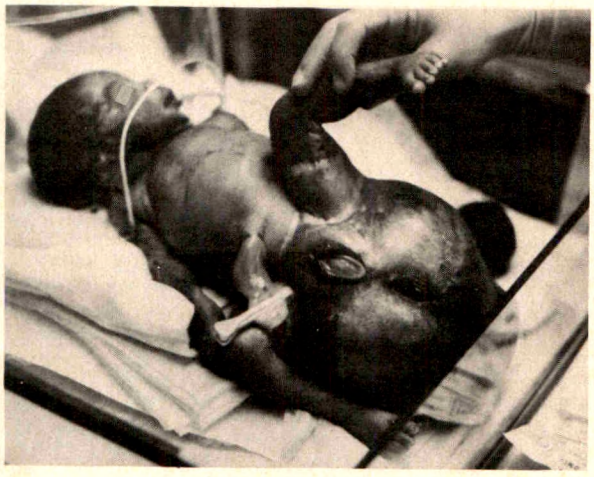

Fig. 3. Premature infant with large sacrococcygeal teratoma. Note forward displacement of anus. Tumor mass comprised 1,450 grams of 2,970 gram birth weight.

Polyhydramnios increased with uterine fundal height reaching 41 cm. Amniocentesis was performed 1 week after hospitalization because of incapacitating abdominal discomfort, and 300 ml of amniotic fluid was withdrawn. This fluid had a lecithin/sphingomyelin (L/S) ratio of 1:2, creatinine concentration of 1.8 mg/dl, and alpha fetoprotein concentration of 0.13 mg/dl. Relief of her discomfort was only partial and temporary. Repeat amniocentesis was necessary 2 days later, at which time 500 ml of fluid were withdrawn without incident. Because of the fear of premature labor, maternal betamethasone was used to induce fetal pulmonary maturity. Premature labor did ensue 2 days after the second amniocentesis. Cesarean section was performed, with delivery of a 2,970 gram female infant. A sacrococcygeal teratoma measuring 14 cm in diameter was present (Fig. 3). No other anomalies were found. The infant developed mild respiratory distress. The tumor was resected 5 days after delivery and weighed 1,450 grams.

Prenatal diagnosis of sacrococcygeal teratoma (SCT) is rare. The tumor most commonly is detected on routine examination of the neonate. However, large tumors may obstruct labor and be suspected on vaginal examination after delivery of the fetal head and upper body. In such cases the infant almost invariably dies before delivery can be completed.

Previous reports of fetal malformations diagnosed by ultrasonography appear to have made the diagnosis of SCT only in retrospect.[1, 2] In none of the three cases previously reported was the diagnosis of SCT used to assist in delivery of a living infant; one of these fetuses died antepartum and the other two died during labor and vaginal delivery.

In the case reported, the presence of polyhydramnios led to ultrasonography. The association between major fetal malformations and polyhydramnios is well known, and the presence of fetal anomaly should be considered in the evaluation of polyhydramnios. The bizarre and complex ultrasonographic characteristics and the location of the fetal tumor in this case were thought to be strongly indicative of SCT. The possibility of lumbosacral meningomyelocele was considered, but careful ultrasonographic examination of the fetal vertebral column showed no suggestion of spina bifida, and the amniotic fluid alpha fetoprotein concentration was within normal limits.

This case report confirms that SCT can be diagnosed prenatally. When such a tumor is diagnosed, the pediatrician and pediatric surgeon can be alerted even prior to delivery, and definitive management can be initiated at the earliest possible opportunity. Cesarean section delivery was elected in this case to prevent both fetal and maternal trauma and to avoid the high rate of perinatal death which accompanies vaginal delivery of such an infant.

Lidocaine interference in lecithin/sphingomyelin ratios

ALAN E. CLAGUE, M.B., B.Sc., F.R.C.P.A.
HEATHER M. McGEARY, B.Sc., M.A.A.C.B.

Pathology Department, Royal Brisbane Hospital, Queensland, Australia

LIDOCAINE is commonly used as a local anesthetic for amniocentesis and residual lidocaine may contaminate the amniotic fluid specimen if the same syringe is used for the local anesthetic and the specimen. We found interference in estimating the lecithin/sphingomyelin (L/S) ratio (according to the method of Gluck and Kulovich[1]) of an amniotic fluid contaminated with lidocaine. We report the case and our subsequent investigations of the phenomenon.

An L/S ratio was performed on a woman, gravida 2, para 1, at 37 weeks' gestation who had both anti-C and -D antibodies. The chromatography pattern of the extracted phospholipids could not be interpreted because of an interfering substance which smeared from the sphingomyelin region to the phosphatidyl inositol spot. Initially it had a pink color, but this darkened with further charring. A history of residual lidocaine present in the collecting syringe was elicited.

Lidocaine (as 1% lidocaine hydrochloride) was diluted in water and pH adjusted to give a range of values from 6.0 to 9.5. Lidocaine was added to fresh am-

Table I. L/S ratios of amniotic fluids, and the same fluid after addition of lidocaine

Initial specimen	*Specimen containing 0.08% lidocaine*
1.4	1.9
1.4	2.1
1.6	2.2
1.0	1.1
1.7	2.1

niotic fluids (pH 7.0 to 7.2) with L/S ratios <2.0. L/S ratio estimations were performed on the aqueous lidocaine solutions and the treated amniotic fluid specimens. Lidocaine was not extracted appreciably from aqueous solutions with a pH <8.5. At pH >8.5 it appeared as a pink spot, turning brown with further heating in the region of lecithin. It was, however, readily extracted from amniotic fluid at pH 7.2. At a level of 0.08% (corresponding to a contamination of 0.25 ml of 1% lidocaine in a 3 ml specimen) the results shown in Table I were observed.

At a level of 0.3%, lidocaine appeared as a smear from the sphingomyelin region to the phosphatidyl inositol area, but mainly in the lecithin region. The smear appeared pink initially, then became brown with further heating. The color change phenomenon was not observed at lower concentrations.

Contamination with lidocaine is a potentially serious source of interference in estimation of L/S ratio according to the method of Gluck and Kulovich,[1] as minimal contamination may convert an immature to a mature result. At this low level its presence would pass undetected and the incorrect result would be issued. Since lidocaine has a pKa of 7.9 and is not extracted from aqueous solution at pH 7.0 to 7.2 (the pH of amniotic fluid), the extraction from amniotic fluid is most likely due to formation of ion pairs with phospholipids.

CORRESPONDENCE

Fetal hemorrhage following blood samplings and use of vacuum extractor

To the Editors

I have read with interest the case report by Drs. Roberts and Stone (AM. J. OBSTET. GYNECOL. 132:109, 1978). This complication is certainly an unusual one; we never had a case of exsanguination among more than 4,000 consecutive (mostly elective) vacuum extractions of fetuses monitored with a clip electrode fixed to the scalp and from which a micro– blood sample was taken at full dilatation. If the stab wound bleeds rather profusely, we apply pressure through the amnioscope with a tampon. If this measure proves insufficient, an extra clip is applied over the scalp wound. To date, these preventive measures have invariably been successful.

In vitro fertilization in humans

To the Editors:

The issue addressed in this letter is current and consequently it is circumscribed by emotion and a distinct paucity of data. Notwithstanding these shortcomings the query is: What increase in genetic abnormalities can be expected in human embryos as a result of in vitro fertilization? The scope of our response will be limited to the spermatozoon and an analysis of the potential effect of using ejaculated human spermatozoa for in vitro fertilization.

First recognize that the constancy in human sperm deoxyribonucleic acid (DNA) among gametes of a single ejaculate is highly variable.[1] Here the coefficient of variation ranges from 8.5% to 24.3% with a mean of 13.1%. For bull spermatozoa the coefficient of variation is 10.6%[2] Thus, in a human male subject the number of genetically unbalanced gametes may range between 13 and 41 $\times$ 10^6 cells per ejaculate. If one assumes that the vast majority of these cells are alive and motile and that they take part in fertilization in numbers proportionate to those reaching the egg, regardless of genome balance, which on the basis of evidence[3] from other mammals are reasonable assumptions, then the percentage of recognizable chromosomal aberrations in the human conceptus resulting from fertilization by genetically unbalanced spermatozoa should make up a measurable share of the total, estimated to be approximately 7% of all known pregnancies.[4] Jacobs'[4] estimate is that approximately one third or, stated differently, 2% of all known pregnancies may be effected by genetically unbalanced spermatozoa. Yet the reported genetic variation in spermatozoan DNA among gametes in a human ejaculate averages 13%, approximately six times greater than the estimated chromosomal aberrations in humans effected by genetically unbalanced spermatozoa. This can only mean that either the estimates are incorrect or there is strong selective pressure against spermatozoa harboring unbalanced genomes.

It is likely that the estimated percentage of human chromosomal aberrations effected by genetically unbalanced spermatozoa is incorrect, due in part to unaccounted early embryonic losses,[3] but it is unlikely to be off by a factor of 6. Consequently some selective pressure against genetically unbalanced spermatozoa in an ejaculate must occur. The only possible site where selection could take place is within the female reproductive tract. Although this idea was proposed over a decade ago[5] there has been little scientific effort to test the hypothesis. In the rabbit it has been shown that transport through the female reproductive tract reduces the number of ejaculated diploid spermatozoa by approximately 79%[6] and that oviducal spermatozoa have a fertilization advantage over ejaculated spermatozoa in a heterospermic insemination.[7]

If one assumes the difference between the values for genetic variation in a human ejaculate and the recognizable chromosomal aberrations in the human population results from selection within the female tract and calculates the percent of unbalanced gametes selected against, this value (~85%) is strikingly close to the reported reduction of rabbit diploid spermatozoa. Such a comparison, when based on assumptions, proves nothing but should illustrate the potential increase in genetic anomalies that could result from in vitro fertilization. If female tract selection against male gamete anomalies in the human approaches 80%, then a sixfold increase in the probability of fertilization by a genetically unbalanced sperm in vitro would be expected. Whether or not this is correct is unknown, but it certainly emphasizes that human gamete physiology

must be studied more intensely from a fundamental viewpoint.

Corticosteroids and respiratory distress syndrome

To the Editors:

I read with interest the article by Morrison and colleagues in the June 15, 1978, issue of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY on corticosteroids and respiratory distress syndrome (RDS). They are to be complimented on the meticulous fashion in which the study was performed; however, there were several points I hope they can clarify.

I noted that the study was performed between the years 1972 and 1975. During this time there was little or no literature discussing the association between length of time of membrane rupture and the development of RDS. Additionally there was nothing in the literature about the association of the use of various β-mimetic agents and acceleration of fetal pulmonary maturity. In Table I of the article, although patients in premature labor in both groups seemed to be equally distributed between treatment and control groups there was no mention of duration of membrane rupture and the distribution of these patients in reference to the length of membrane rupture. Additionally, several patients received isoxsuprine and ritodrine in the study, and no mention of the distribution of these patients between treatment and control groups was made.

Should it turn out that in their study both of these factors were equally distributed between Groups I and II, more validity could be placed on the study. Would Dr. Morrison and colleagues please tell us the above-mentioned distributions?

Reply to Dr. Myers

To the Editors:

In responding to Dr. Myers' letter concerning our study,[1] we thank him for his critical review. He is correct in stating that the literature is sparse concerning the relationship of RDS to premature rupture of the membranes or the use of beta-sympathomimetic agents. Indeed, there was even less in the literature during the planning phases of our study in 1970 and 1971. Because this was a new area of interest we chose to collect pertinent data on many variables including status of membranes and use of tocolytic drugs.

The length of time of rupture of membranes was unequally distributed between the two groups (Table I). However, the maldistribution shows an *increase* in the number of patients in the control group who had ruptured membranes for a longer period of time. We interpreted these data as demonstrating that ruptured membranes did not statistically *decrease* the incidence of RDS. It is possible, however, that the small sample size obviated this interpretation since other authors with larger series have reported rupture of membranes for greater than 24 to 48 hours to be a positive correlate of lung maturity.[2, 3] We did not report this in our original article, but included it in a subsequent report dealing with the lecithin/sphingomyelin ratio values from these patients.[4] Therefore, rupture of the membranes in our series did not bias the study conclusion that the steroid was effective since, if anything, it would have decreased the incidence of RDS in the control group rather than in the study group.

The use of various tocolytic agents (alcohol, ritodrine, or isoxsuprine) was equally distributed in those patients who were admitted in premature labor *with* or *without* ruptured membranes. Also the use of these drugs was equally distributed between the control and study groups (Table II). While other workers have shown a positive correlation (decrease in RDS),[5, 6] we could not find any influence of the beta-sympathomimetic agents on pulmonary surfactant induction although the numbers were small in each category. Currently, we are assessing the effect of several beta-sympathomimetic drugs on the induction of fetal lung maturity in animals[7] as well as assessing the effects of isoxsuprine on pulmonary surfactant induction in a large clinical trial.[8]

Hopefully, continued investigation in this field will lead to the elucidation of the two points raised by Dr.

Table I. Duration of premature ruptured membranes*

Group	Duration		
	<24 hr.	*24-48 hr.*	*>48 hr.*

Myers. As to the validity placed on our study, I am afraid that these two questions, although answered, will not contribute to that end. Only a large comprehensive trial such as the one being conducted by the National Heart, Lung and Blood Institute will assess: (1) the advisability of the use of steroids in a patient at risk for premature delivery, (2) the potential short-term hazards of steroids for mother and fetus, and (3) most importantly, the long-range sequelae, if any, to the infant. Hopefully, answers to these issues will be forthcoming in the near future.

New! Available for the first time

The ten-year **cumulative author and subject index** to volumes 100-129 (1968-1977) of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY is now available for your journal collection. It is a complete and comprehensive reference guide to over 28,000 pages of authoritative articles published in the Journal during the past ten years.

The world-renowned "Gray Journal" is the oldest specialty journal devoted to obstetrics and gynecology.

Now these influential papers, appearing between 1968-1977, have been cross-referenced to include over 23,100 subject entries. Each entry lists the complete article title, author(s), volume, page, and year of publication.

The author index lists more than 13,850 contributors from this period, along with respective article title, author-to-author referral, volume, page, and publication date.

The 479-page index is handsomely presented in a rust and gold cloth-cover volume. It is a must for every library concerned with obstetrics and gynecology. Send for your copy of this valuable reference today!

Flagyl® (metronidazole) 250 mg.

Warning
Metronidazole has been shown to be carcinogenic in mice and possibly carcinogenic in rats. (See *Warnings*.) Unnecessary use of the drug should be avoided. Its use should be reserved for the conditions described in the *Indications* section.

Indications: For the treatment of symptomatic trichomoniasis in both females and males when the presence of the trichomonad has been confirmed by appropriate laboratory procedures (wet smears and/or cultures). Also for the treatment of asymptomatic females when the organism is associated with endocervicitis, cervicitis, or cervical erosion. *T. vaginalis* infection is a venereal disease and therefore, asymptomatic sexual partners of infected patients should be treated simultaneously if the organism is present. The decision to treat an asymptomatic male partner who has a negative culture or smear, or one in whom no culture has been attempted, is an individual one. In any event, the consort should be treated with Flagyl in cases of reinfection. Flagyl is also indicated for acute intestinal amebiasis (amebic dysentery) and for amebic liver abscess.

Contraindications: Evidence or history of blood dyscrasia, active organic disease of the CNS, the first trimester of pregnancy and a hypersensitivity to metronidazole.

Warnings: Flagyl should not be used in the first trimester of pregnancy (see *Contraindications*). Use with discretion during the second and third trimesters of pregnancy and restrict to those pregnant patients not cured by topical measures. Flagyl (metronidazole) is secreted in the breast milk of nursing mothers. It is not known whether this can be injurious to the newborn. If used during lactation, an alternative method of feeding may be elected.

Note: Tumorigenicity Studies in Rodents. Metronidazole has shown evidence of tumorigenic activity in a number of studies involving chronic, oral administration in mice and rats.

Most prominent among the effects in the mouse was the promotion of pulmonary tumorigenesis. This has been observed in all five reported studies in that species, including one study in which the animals were dosed on an intermittent schedule (administration during every fourth week only). The published results of one of the mouse studies indicate increases in the incidence of malignant lymphomas as well as pulmonary neoplasms associated with lifetime feeding of the drug. All these effects are statistically significant.

Two long-term toxicity studies in the rat have been completed. There was a statistically significant increase in the incidence of various neoplasms, particularly mammary tumors, among female rats administered metronidazole over that noted in the concurrent female control groups.

Two lifetime tumorigenicity studies in hamsters have been performed and reported to be negative.

Metronidazole has been reported to potentiate the anticoagulant effect of coumarin and warfarin resulting in a prolongation or prothrombin time. This possible drug interaction should be considered when Flagyl is prescribed for patients on this type of anticoagulant therapy.

Precautions: Mild leukopenia has been reported during Flagyl use; total and differential leukocyte counts are recommended before and after treatment with the drug, especially if a second course is necessary. Avoid alcoholic beverages during Flagyl therapy because abdominal cramps, nausea, vomiting, headaches and flushing may occur. Discontinue Flagyl promptly if abnormal neurologic signs occur. Exacerbation of moniliasis may occur. In amebic liver abscess, aspirate pus during metronidazole therapy.

Adverse Reactions: Nausea, headache, anorexia, vomiting, diarrhea, epigastric distress, abdominal cramping, constipation, a metallic, sharp and unpleasant taste, furry tongue, glossitis and stomatitis possibly associated with a sudden overgrowth of *Candida*, exacerbation of vaginal candidiasis, an occasional reversible moderate leukopenia, dizziness, incoordination and ataxia, numbness or paresthesia of an extremity, fleeting joint pains, confusion, irritability, depression, insomnia, mild erythematous eruptions, "weakness," urticaria, flushing, nasal congestion, dryness of the mouth, vagina or vulva, pruritus, dysuria, cystitis, a sense of pelvic pressure, dyspareunia, fever, polyuria, incontinence, decrease of libido, proctitis, pyuria and darkened urine have occurred in patients receiving the drug. Patients receiving Flagyl may experience abdominal distress, nausea, vomiting, flushing or headache if alcoholic beverages are consumed. The taste of alcoholic beverages may also be modified. Flattening of the T-wave may be seen in ECG tracings.

Dosage and Administration: ***For Trichomoniasis:*** The recommended dosage for both male and female is one 250-mg. tablet orally three times daily for seven days. When repeat courses of the drug are required, it is recommended that an interval of 4 to 6 weeks elapse between courses and that the presence of the trichomonad be reconfirmed by appropriate laboratory measures. Total and differential leukocyte counts should be made before, during and after retreatment. The male consort should be treated in any event in cases of reinfection.

For Amebiasis: *Adults:* For acute intestinal amebiasis, 750 mg. orally three times daily for 5 to 10 days.

For amebic liver abscess: *Adults:* 500 mg. or 750 mg. orally three times daily for 5 to 10 days.

Children: 35 to 50 mg./kg. of body weight/24 hours, divided into three doses, orally for 10 days.

If men suffered from the symptoms of trichomoniasis, they'd appreciate Flagyl.®

(metronidazole)

Women with trichomoniasis have been grateful for the benefits of Flagyl therapy for over a decade. Most men have no symptoms and are not even aware that they have contracted trichomoniasis, so they rarely appreciate Flagyl. Unless both sexual partners are diagnosed and treated simultaneously, reinfection from the consort is a probability (the "ping-pong" effect).

In the female, trichomoniasis is a multiorgan disease. Trichomonads invade the vagina and are often deeply entrenched in the endocervix, Skene's and Bartholin's glands, the urethra and the bladder. Only the systemic action of Flagyl can eliminate trichomonads from these sequestered sites.

In the male, only Flagyl can effectively eliminate trichomonads from the male genitourinary tract.

Thus, for the female Flagyl is the treatment of choice. For the male it is the only choice. And that's something they both can appreciate!

Today's t_ _nag_r exp_ _cts a lot more than medicine from her doctor.

The plight of today's teenager in these socially turbulent times is often precarious at best. According to a recent national survey, there has been a 30% increase in teenage sexual activity in the last five years.[1] Also, half of all out-of-wedlock births are attributed to teens. Up to two-thirds of these are unwanted, unplanned births.[2] Trapped in the midst of rapidly changing sexual mores, the teenager is further beset by uncertainty, timidity, ignorance, and misinformation.

That's why today's younger patient needs and deserves thorough counseling — underlined by compassion, reassurance, and trust — in many areas. These range from the basic facts of life, in some cases, to more serious subjects like venereal disease. But, no issue is more sensitive, or more in need of physician/patient exploration than that of contraception.

Today, contraceptive counseling often culminates in the selection of a low-dose oral contraceptive like Brevicon. Brevicon offers a rate of efficacy comparable to higher-dose formulations and its incidence of menstrual irregularities is low. In 16,345 cycles among 1,168 patients, there were 0.22 pregnancies per 100 woman years. Breakthrough bleeding occurred in 5.1% of cycles, and amenorrhea in 1.0% of cycles. Dropout rate due to menstrual irregularities during the crucial first three months was 3.4%.

Counseling, compassion, and Brevicon — a good combination for many of today's teenage patients.

Brevicon® tablets **A sign of the times**

(norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)

1. Zelnik, M. and Kantner, R.: Sexual and Contraceptive Experience of Young Married Women in the United States, 1976 and 1971. Family Planning Perspectives. Vol. 9, No. 2, March/April 1977.

2. Monthly Vital Statistics Report: Natality Statistics, National Center for Health Statistics, Vol. 26, No. 5, September 1977.

Note: Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be fully aware of the prescribing information for this product.

(norethindrone 0.5 mg. with ethinyl estradiol 0.035 mg.)

Brevicon® 28-Day Tablets

(21 norethindrone 0.5 mg. with ethinyl estradiol 0.035 mg. tablets followed by 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

INDICATIONS O.C.s are indicated for the prevention of pregnancy. The drop-out rate for medical reasons, as observed in the clinical trials conducted with BREVICON, appears to be somewhat higher than observed with higher dose combination products. The dropout rate due to menstrual disorders and irregularities was also somewhat higher, dropouts being equally split between menstrual disorders and irregularities and other medical reasons attributable to the drug. *DOSE-RELATED RISK OF THROMBOEMBOLISM FROM O.C.s.* Studies have shown a positive association between the dose of estrogens in O.C.s and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The O.C. product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of O.C.s should be started on preparations containing 0.05 mg or less of estrogen.

CONTRAINDICATIONS 1. Known or suspected pregnancy (see Warning No. 5). 2. O.C.s should not be used in women who have or have had any of the following conditions: a. Thrombophlebitis or thromboembolic disorders. b. Cerebral vascular or coronary artery disease. c. Markedly impaired liver function. d. Known or suspected carcinoma of the breast. e. Known or suspected estrogen dependent neoplasia. f. Undiagnosed abnormal genital bleeding.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from O.C. use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use O.C.s should be strongly advised not to smoke.

The use of O.C.s is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing O.C.s should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of O.C.s is well established. One British study demonstrated an increased relative risk for fatal venous thromboembolism; two British and three American studies demonstrated an increased relative risk for non-fatal venous thromboembolism. These studies estimate that users of O.C.s are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke, which had not been shown in prior British studies. In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the relative risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers. A British long-term, follow-up study reported in 1976 a highly significant association between O.C. use and stroke. Another British long-term, follow-up study had suggested such an association in 1974, but the number of cases was too small to estimate the risk. MYOCARDIAL INFARCTION. An increased relative risk of myocardial infarction associated with the use of O.C.s has been reported, confirming a previously suspected association. One study conducted in the United Kingdom found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an O.C. user or not. O.C.s, however, were found to be an additional risk factor. In terms of relative risk, it has been estimated that O.C. users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. O.C. users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, and about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the number of cigarettes smoked is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. (The estimates are based on British vital statistics which show acute myocardial infarction death rates 2- to 3-times less than in the U.S. for women in these age groups; consequently, actual U.S. death rates could be higher.) The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in O.C.s. Preparations containing 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been supported by a study in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only O.C.s have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASE. A large British prospective study estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of O.C.s according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for O.C. users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000). The risk is concentrated in older women, in those with a long duration of use, and in cigarette smokers, and may persist after discontinuation of O.C. use. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of O.C.s) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The findings of this analysis are shown in Table 1 below. The study concluded that the mortality associated with all methods of birth control is low and below that of childbirth, with the exception of O.C.s in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates given would be about double; for "light" smokers (less than 15 cigarettes a day), about 50 percent.) The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The study also concluded that O.C. users who smoke, especially those over the age of 30, have a greater mortality risk than O.C. users who do not smoke.

TABLE 1. *The annual number of deaths associated with control of fertility and no control per 100,000 nonsterile women by regimen of control and age of women are:*

	15-19	20-24	25-29	30-34	35-39	40-44
No method	5.6	6.1	7.4	13.9	20.8	22.6
Abortion only	1.2	1.6	1.8	1.7	1.9	1.2
Pill only—nonsmokers	1.3	1.4	1.4	2.2	4.5	7.1
Pill only—smokers	1.5	1.6	1.6	10.8	13.4	58.9
IUDs only	0.9	1.0	1.2	1.4	2.0	1.9
Traditional contraception only	1.1	1.6	2.0	3.6	5.0	4.2
Traditional contraception and abortion	0.2	0.2	0.3	0.3	0.3	0.2

The risk of thromboembolic and thrombotic disease associated with O.C.s [illegible] increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. Based on the data currently available, the following table gives a gross estimate of the risk of death from circulatory disorders associated with the use of O.C.s:

TABLE 2. *Smoking habits and other predisposing conditions – risk associated with use of O.C.s*

Age	Below 30	30-39	40+
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (No predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

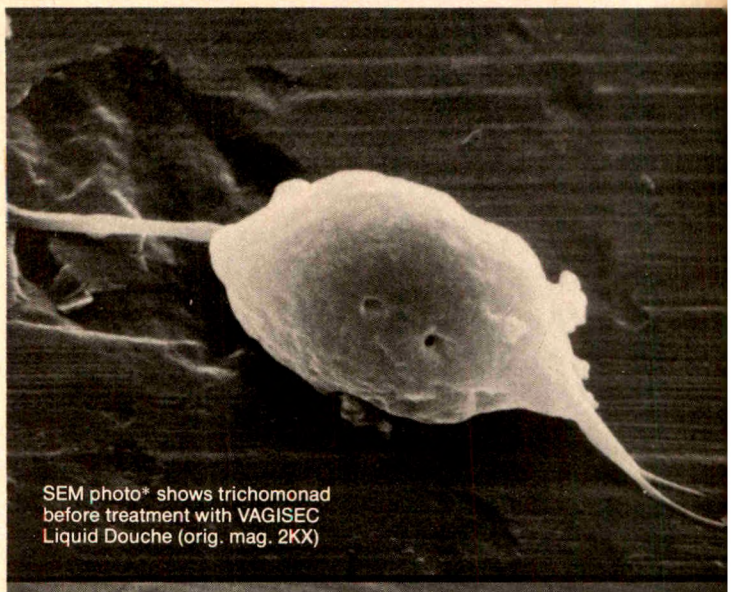
A—Use associated with very high risk. C—Use associated with moderate risk.
B—Use associated with high risk. D—Use associated with low risk.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of post-surgery thromboembolic complications has been reported in O.C. users. If feasible, O.C.s should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. Among patients with thromboembolic disease, the results of retrospective studies suggest the possibility of an increased risk for users who are of blood types A, B, or AB, as compared with those of type O. *Ocular Lesions:* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of O.C.s. Discontinue O.C. medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of certain adenomas, benign or malignant, such as those of the breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently contained in O.C.s, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies have reported an increased relative risk (3.1 to 13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women who took estrogen replacement medication to relieve menopausal symptoms. One publication reported on the first 30 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on O.C.s. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time O.C.s were first given, polycystic ovaries) nearly all occurred in women who had used a sequential O.C. These products are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only O.C.s, although individual cases have been reported. Several studies have shown no increased risk of breast cancer to women taking O.C.s or estrogens. In one study, however, while no overall increased risk of breast cancer was noted in women treated with O.C.s, a greater risk was suggested for the subgroups of O.C. users with documented benign breast disease and for long-term (2-4 years) users. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. A reduced occurrence of benign breast tumors in users of O.C.s has been well documented. In a prospective study of women with cervical dysplasia, there was an increase in severity and of conversion to cancer *in situ* in O.C. users compared with nonusers. This became statistically significant after 3 to 4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to be predictive of progression after prolonged exposure. There have been other reports of microglandular hyperplasia of the cervix in users of O.C.s. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with O.C.s. Close clinical surveillance of all women taking O.C.s is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use O.C.s instead of other methods of contraception. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with O.C. use. This has been reported in short-term as well as long-term users of O.C.s. One study showed that O.C. formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Two studies relate risk with duration of use, the risk being much greater after 4 or more years of use. Although it is an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may clearly show a focal defect. Hepatic arteriography may be a useful procedure in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that O.C.s further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use O.C.s instead of other methods of contraception. Furthermore, a high percentage of women exposed to diethylstilbestrol (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported following use of sex hormones, including O.C.s, in pregnancy. In one case-control study it was estimated that there was a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (O.C.s, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including O.C.s, during early pregnancy occurred at a rate of 18.2 per 1,000 births, compared to 7.8 per 1,000 for children not so exposed *in utero*. These results are statistically significant. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing O.C.s. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping O.C.s is unknown. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if progestogen-only O.C.s are used) and further use of O.C.s should be withheld until pregnancy has been ruled out. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue O.C.s with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. 6. *Gall Bladder Disease:* Studies report an increased risk of gall bladder disease in users of O.C.s or estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In another study an increased risk was apparent between 6 and 12 months of use. 7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on O.C.s. For this reason, prediabetic and diabetic patients should be carefully observed while receiving O.C.s. An increase in triglycerides and total phospholipids has been observed in patients receiving O.C.s. The clinical significance of this finding is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with O.C. use. In some women, hypertension may occur within a few months of beginning O.C. use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in O.C. users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, a history of toxemia or elevated blood pressure during pregnancy, a familial tendency to hypertension or its consequences, or a history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevation of blood pressure when given O.C.s and therefore, should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, the clinical implications of elevations should not be ignored and close surveillance is indicated, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after discontinuation of the O.C. 9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of O.C.s and evaluation of the cause. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses are frequent reasons for patients discontinuing O.C.s. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an O.C. with a higher estrogen content, while potentially useful in minimizing menstrual irregularity should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of O.C.s. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased prevalence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing O.C.s in comparison with those discontinuing other methods of contraception. The impairment appears to be independent of the duration of use of the preparations. While the impairment diminishes with time, there is still an appreciable difference in the results in nulliparous women for the O.C. and non-O.C. groups 30 months after discontinuation of birth control. For parous women the difference is no longer apparent 30 months after cessation of contraception. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in progestogen-only O.C. failures, the ratio of ectopic to intrauterine pregnancies is higher than in women who are not receiving O.C.s, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* O.C.s given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in O.C.s has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast fed child have not been determined. If feasible, the use of O.C.s should be deferred until the infant has been weaned. **PRECAUTIONS** *GENERAL* 1. A complete medical and family history should be taken prior to the initiation of O.C.s. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, O.C.s should not be prescribed for longer than 1 year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking O.C.s should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. 4. O.C.s may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving O.C. therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. O.C. users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is unknown. 8. Serum folate levels may be depressed by O.C. therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping O.C.s, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of O.C. therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing O.C.s. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. *DRUG INTERACTIONS* O.C.s may be rendered less effective by virtue of drug interaction with rifampin, isoniazid, ampicillin, neomycin, penicillin, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers and antimigraine preparations. O.C.s may alter the effectiveness of other types of drugs, such as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., quanethidine), vitamins and hypoglycemic agents. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **ADVERSE REACTIONS** An increased risk of the following serious adverse reactions has been associated with the use of O.C.s (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis or optic neuritis. The following adverse reactions have been reported in patients receiving O.C.s and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps), dysmenorrhea, infertility after discontinuation of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, change in corneal curvature (steepening) change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution in lactation when given immediately postpartum, premenstrual jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors. The following adverse reactions have been reported in users of O.C.s, and the association has neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function. **INFORMATION FOR THE PATIENT** (See Patient Package Insert)

Destroys Trichomonads in 15 seconds

Immediate symptomatic relief

In vitro studies[1,2] show that within 15 seconds of contact, VAGISEC Douche permeates the trichomonad's outer membrane and weakens its cell wall, causing it to swell and die.



VAGISEC Douche/ VAGISEC PLUS Suppositories

regimen for the treatment of trichomoniasis... or mixed vaginal infections

VAGISEC Douche acts on the trichomonads directly—far faster than most systemic medication. It penetrates the vaginal creases and folds; cleanses and dissolves mucinous material; and prevents buildup of microorganisms. Relief from itching, burning, leukorrhea and malodor is almost immediate.

VAGISEC PLUS Suppositories combines the same proved trichomonacide with effective antibacterial action against susceptible strains of staph, strep and coliform organisms,[3] and is particularly useful in mixed infections.

The combination douche/suppositories regimen is recommended in all cases, except during pregnancy, when douching is not recommended. Strict adherence to the treatment program is essential for therapeutic success.

SEM photo* shows trichomonad before treatment with VAGISEC Liquid Douche (orig. mag. 2KX)

15 seconds after treatment, photo shows cell wall destruction and loss of flagella (orig. mag. 5KX)

VAGISEC Liquid Douche/VAGISEC PLUS Suppositories
Contraindications: Douching is not recommended during pregnancy. VAGISEC Liquid Douche and VAGISEC PLUS Suppositories are spermicidal and should not be used on days when the patient is trying to conceive. **Precautions:** *Therapeutic Treatment:* Recurrence of vaginitis often indicates extravaginal foci or infection in cervical, vestibular and urethral glands, etc., or reinfection by the sexual partner. During treatment, patient should refrain from intercourse or the partner should wear a prophylactic. To prevent flare-ups after completion of therapy and for continued vaginal cleanliness, the patient is advised to continue with VAGISEC Liquid as a regular douche, but no more than twice weekly unless otherwise directed by physician. **Side Effects:** No significant side effects reported to date. Any minor irritation is alleviated by discontinuance of douche for a single day. **Administration and Dosage:** *Office Treatment (Adult):* For the treatment of vaginal trichomoniasis and mixed vaginal infections, best results are obtained by scrubbing the vagina with VAGISEC Liquid, diluted 1:100, by the physician in the office; 3 scrubs the first week, 2 the second. A suppository is inserted after each office scrub in the Liquid/Suppository regimen. Patient should be instructed to continue treatment at home. *Home Treatment:* Liquid/Suppository regimen: In all instances, the combination douche and suppositories are recommended for home use. The usual home treatment is VAGISEC Liquid Douche in the morning, followed by a VAGISEC PLUS Suppository inserted deep in the vagina and a second suppository inserted in like manner at bedtime, daily, for a period of 14 days. For those physicians who feel it important to treat the patient through the complete menstrual cycle, the Liquid/Suppository regimen may be continued throughout the month. It is advisable to continue treatment through two menstrual periods. Treatment should be omitted the night and morning preceding an office visit. Patients should be reexamined 3 days after home treatment has been discontinued. The full course of therapy must be completed to eliminate the infecting microorganisms from the vagina. In chronic or stubborn cases, therapy may be repeated with no interval between courses. During treatment, patient should refrain from intercourse, or the partner should wear a prophylactic. No patient should be considered cured until vaginal smears or cultures, taken at monthly intervals for 3 months following treatment, show absence of trichomonads and a return to the normal vaginal flora. **How Supplied:** VAGISEC Liquid—4 oz. plastic bottle. VAGISEC PLUS Suppositories—box of 28 3-gram suppositories, foil-wrapped, with inserter. *Federal law prohibits dispensing VAGISEC PLUS suppositories without prescription. More detailed professional information available on request.*

SCHMID PRODUCTS CO.

Vagisec® DOUCHE LIQUID CONCENTRATE

VagisecPlus® SUPPOSITORIES

Each suppository contains
9-aminoacridine HCl 6 mg.
Polyoxyethylene nonyl phenol 5.25 mg.
Sodium edetate .66 mg.
Sodium dioctyl sulfosuccinate 0.07 mg. in a polyethylene glycol base containing glycerin and citric acid

EMPIRIN® COMPOUND
with CODEINE

Each tablet contains: aspirin, 227 mg; phenacetin, 162 mg; and caffeine, 32 mg; plus codeine phosphate in one of the following strengths: #4—60 mg (gr 1); #3—30 mg (gr ½); #2—15 mg (gr ¼); and #1—7.5 mg (gr ⅛). (Warning—may be habit-forming).

In tubal reconstructive surgery, OpMi 7-P/H lets you share the view.

Ideal for reanastomosis of the fallopian tube

Two microsurgeons can perform tuboplastic procedures face-to-face through the same stereo-optics—superb Zeiss optics. Unmatched slimness of the microscope and tilt to 30° provide comfortable co-observation. The fiber-optic co-axial illumination system is exceptionally bright, cool, and shadow-free.

Completely motorized focusing and 1:5 precision zoom system

Truly continuous magnification change, perfectly flat-field, edge-to-edge sharpness, the broadest choice of working distances in increments of 1".

Unique beam splitter

Permits the integration of a still or motion-picture or TV camera to capture, through the microscope optics, the exact area viewed by the surgeons. If the operation calls for three surgeons, a stereo co-observation tube or a second zoom microscope can be attached.

Contact Zeiss today for details or a demonstration.

For the special needs of patients with hard, dry stools

SENOKOT®-S

(standardized senna concentrate and dioctyl sodium sulfosuccinate) **Tablets**

the "S" stands for softener

For patients with hard, dry stools
Hard, dry stools hurt, and may be hazardous by causing straining. SENOKOT-S Tablets offer comfortable relief by softening the stool *and* stimulating its movement.

Provides standardized senna concentrate, a clinically established laxative of choice
Standardized senna concentrate is a gentle, effective neuroperistaltic stimulant with documented effectiveness in thousands of patients. Its virtually colon-specific, gentle, predictable action is generally free of side effects at proper dosage levels.

Provides DSS, the classic stool softener
DSS in SENOKOT-S Tablets complements the laxative effect of standardized senna concentrate by "moistening" and softening the stool for smoother and easier passage.

Comfortable overnight action
With DSS and standardized senna concentrate, SENOKOT-S Tablets provide *both* softness and stimulation for constipated patients with hard, dry stools. Taken at bedtime, SENOKOT-S Tablets usually induce predictable, comfortable evacuation the next morning.

You're looking at the only medical reason to recommend a douche.

Monilial vaginitis before Trichotine

Monilial vaginitis after Trichotine

When douching can enhance therapy of vaginitis, as in the photographs above, it has a definite place in medicine. And such evidence, as described by numerous clinical investigators over the years, is exactly the reason Trichotine® receives extensive professional recommendation.

By clearing away obstructive vaginal discharge, Trichotine affords better access to infected mucosa during topical vaginitis therapy and speeds symptomatic relief when used with systemic agents.

One investigator, for example, found that "relief of itching and leukorrhea is prompt and enhances the results obtained with the specific therapy."[1] In subsequent studies[2,3] of patients with vaginitis, others have confirmed this rapid symptomatic relief.

Further, following surgical procedures such as cervical cryosurgery, douching with Trichotine has "...proved to be an effective adjunct in...reducing vaginal discharge, irritation, discomfort and patient complaints."[4] Similar benefits were reported in cervical cauterization,[5] in acute inflammatory[6] and chronic pelvic disease.[7]

Cleanses better than acid douches/Works differently than iodophor douches.

Alkalinity enhances the detergent action of Trichotine—by lowering surface tension and increasing mucolytic action. This results in more thorough vaginal cleansing than with acid douches.[8,9] And, unlike acid douches, Trichotine won't coagulate and precipitate vaginal debris.[8] Or burn as acid douches tend to do.

Unlike iodophor douches, Trichotine doesn't upset the vaginal flora by introducing broad-spectrum antimicrobials. Its actions are limited to those you expect from an adjunctive douche: mucolytic, antipruritic, detergent and deodorizing.

Trichotine: The more you know about it, the more professional reasons you have to recommend douching.

A low level
of estrogen with
a high level of
patient acceptance

"In deciding which combination drug to initially prescribe it is best to utilize the combination pill with the lowest effective dose and an acceptable level of side effects."

Mishell, D.: Current Status of Oral Contraceptive Steroids, Clin. Obstet. Gynecol. *19*:743-764 (December) 1976.

Choose an oral contraceptive she'll stay with.

- Proven effectiveness with excellent cycle control
- Low dropout rate due to breakthrough bleeding and spotting (based on 2,256 patients)*

Months of use	1	2	3	6	9	12
Discontinuation (cumulative) per 100 woman-years of use	0.7	1.1	2.0	3.0	3.5	4.2

*Data on file, G. D. Searle & Co.

- Minor side effects uncommon
- Low incidence of cramping, nausea, weight gain, breast tenderness, and irritability
- Simplified schedule with calendarized Compack®
- Excellent record of continuation

Please see the next page for a brief summary of prescribing information.

Demulen®

(ethynodiol diacetate 1 mg., ethinyl estradiol 50 mcg.)

...She'll stay with it.

Serious as well as minor side effects have been reported with the use of oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptoms of serious disease or conditions and discontinue oral contraceptive therapy when appropriate. The physician should be fully familiar with the complete prescribing information for this product.

SEARLE

Indication and usage—For prevention of pregnancy. Pregnancy rate using products with ≥35 mcg. ethinyl estradiol or ≥50 mcg. mestranol is <1/100 woman-years. With ≤35 mcg. ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. Dose-related Thromboembolic Risk—One study showed positive association between OC estrogen dose and thromboembolic risk. Thus, it is prudent and in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing the least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new OC users on ≤50 mcg. estrogen.

Contraindications—Thrombophlebitis, thromboembolic disorders, cerebral vascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal vaginal bleeding; markedly impaired liver function; past or present, benign or malignant liver tumors.

Warnings

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke.

OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. Thromboembolic disorders and other vascular problems—Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased relative risk for fatal venous thromboembolism, 2 British and 3 U.S. studies increased relative risk for nonfatal venous thromboembolism. Two U.S. studies showed increased relative risk for stroke, not shown in prior British studies. It was estimated OC users were 2–11 times more likely than nonusers to manifest these diseases without evident cause. In a British study of idiopathic deep vein thrombosis and pulmonary embolism, projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. In a British mortality study, overall excess mortality from pulmonary embolism or stroke was 1.3–3.4 deaths/year/100,000 users and increased with age. Cerebrovascular Disorders—In a U.S. study of stroke with and without predisposing causes, risk of hemorrhagic stroke was estimated as 2 times greater and thrombotic stroke 4.0–9.5 times greater in users. Mortality trends in 21 countries indicate that, since OC introduction, changes in mortality from nonrheumatic cardiovascular disease were associated with changes in the prevalence of OC use. The Royal College of GPs reported on its prospective study comparing users and nonusers: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." They reported more superficial and deep vein thrombosis in users. A 1977 analysis showed a 5-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age, smoking and duration of use. In 1976 a British Family Planning Association study found a highly significant association between OC use and stroke though total numbers were small; the increased risk for venous thrombosis and pulmonary embolism was about 4-fold and statistically highly significant. Circulatory disease mortality was significantly greater in users. Myocardial Infarction—An increased risk of MI associated with OC use was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the MI risk, regardless of OC use. OCs were considered an additional risk factor. The excess rate of fatal MI in Britain was about 3.5/year/100,000 users aged 30–39 and 20 for ages 40–44. (These are based on British vital statistics with acute MI death rates 2–3 times less than the U.S. Similar estimates for U.S. are 25.7 for users aged 30–39 with predispositions vs. 1.5 without; for ages 40–44, 86.2 vs. 5.1.) Excess hospitalization rate for nonfatal MI in Britain was about 3.5/year/100,000 users aged 30–39 and 47 for ages 40–44. Smoking is a major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk of fatal MI as nonsmoking users, but a 10–12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30–39		Aged 40–44	
	Users	Nonusers	Users	Nonusers
All smokers	10.2	2.6	62.0	15.9
≥15 cigarettes daily	13.0	5.1	78.7	31.3
<15 cigarettes daily	4.7	0.9	28.6	5.7
Nonsmokers	1.8	1.2	10.7	7.4
Smokers and nonsmokers	5.4	1.9	32.8	11.7

Risk of Dose—Reports of thromboembolism after use of OCs with ≥50 mcg. estrogen received by drug safety committees in Britain, Sweden and Denmark were compared with the distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of thromboembolism, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg. estrogen were associated with higher thromboembolism risk than those with 50–80 mcg. The authors suggested that estrogen quantity may not be the sole factor. Any influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing the same estrogen dose nor between ethinyl estradiol and mestranol. Studies on thromboembolic risk with progestogen-only OCs have not been done. Cases have been reported for these OCs and they are not presumed free of excess risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of thromboembolism was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg. and those with ≥100 mcg. estrogen. For all cases combined, larger doses were associated with only slightly higher relative risk; for idiopathic cases relative risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was no increased risk for cases with predispositions. Thromboembolic risk in users and nonusers increases with age. OCs have been considered an independent risk factor. Excess Mortality from Circulatory Diseases—A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers according to age, smoking habits and duration of use. Excess mortality was 20/100,000 users (5 for ages 15–34, 33 for ages 35–44, 140 for ages 45–49), the risk being concentrated in older women, long-term users, and smokers. Interrelationships of age, smoking and duration of use could not be examined, nor could effects of continuous vs. intermittent use. Though circulatory mortality was increased 10-fold in users of >5 years, all deaths were in women over age 34. Until more under-35 users of 5+ continuous years are available, size of relative risk for this age group cannot be given. Risk of circulatory disease may have persisted after discontinuance of OCs. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (e.g., thromboembolism for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers as a class, light smokers about half. Mortality associated with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with the condom or diaphragm backed up by early legal abortion. Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high, B—high, C—moderate, D—low.	Age: <30	30–39	≥40
Heavy smokers (≥15/day)	C	B	A
Light smokers (<15/day)	D	C	B
Nonsmokers, no predispositions	D	C,D	C
Nonsmokers, with predispositions	C	C,B	B,A

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary artery disease, myocardial infarction, retinal thrombosis, mesenteric thrombosis). Should any of these occur or be suspected, discontinue OCs immediately. A 4–7-fold increased risk of postsurgery thromboembolism was reported in users; if feasible discontinue OCs at least 4 weeks before elective surgery or during prolonged immobilization and do not resume until at least 4 weeks postsurgery. Thromboembolic risk may be increased for users with blood types A, B or AB. **2.** Ocular lesions—Neuro-ocular lesions, such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** Carcinoma—Long-term estrogen in certain animals increases carcinomas such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is now evidence that estrogens increase risk of human endometrial carcinoma. In several case-controlled studies increased relative risk (3.1–13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in 8 U.S. areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions (e.g., irregular bleeding before OCs, polycystic ovaries) occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometrial cancer with combination or progestogen-only OCs, though individual cases have been reported. Studies show no increased breast cancer with OCs or estrogens. However, greater risk was noted in OC users with benign breast disease or long-term (2–4 years) use. Risk of breast cancer with menopausal estrogens rose and further increased with duration of follow-up. Decreased benign breast tumors in OC users is well known. Some studies suggested increased risk of cervical dysplasia, erosion and carcinoma in long-term users; cause and effect is not established. Cervical microglandular hyperplasia has been reported. In summary, there is no confirmed evidence from human studies of increased cancer risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nonfunctional causes and take appropriate diagnostic measures to rule out malignancy. Carefully monitor users with a strong family history of breast cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasia. **4.** Hepatic adenomas, hepatomas, hamartomas, regenerating nodules, focal nodular hyperplasia, hemangiomas, hepatocellular carcinoma, etc. have been associated with OCs. In 1 study OC formulations with high "hormonal potency" were associated with higher risk. Though benign these hepatic lesions may rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Consider such lesions in users with abdominal pain, tenderness, mass or shock. About 25% present with abdominal masses; up to half with acute hemoperitoneum. Routine radiologic and lab studies may not be helpful; liver scans may show a focal defect. Hepatic arteriography or CAT may be useful in diagnosis. Hepatocellular carcinoma was noted in a few users. OCs are contraindicated in case of past or present, benign or malignant liver tumors. **5.** Use in or immediately preceding pregnancy, birth defects, malignancy in offspring—Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. From 30–90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. Males so exposed may develop urogenital defects. Other estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, e.g., multiple anomalies described by VACTERL for vertebral, anal, cardiac, tracheoesophageal, renal and limb defects. There appears preferential expression by males. There was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal pregnancy tests or treatment for threatened abortion). Some exposures were very short, being only a few days. Cardiovascular defects in children exposed to female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8 for those unexposed ($P < .05$). Female sex hormones were used for threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming pregnant soon post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon after stopping OCs. Safety of OCs in pregnancy has not been demonstrated. Rule out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods are missed rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. If pregnancy is confirmed, apprise patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** Gallbladder disease risk surgically confirmed, appeared after 2 years' use and doubled after 4–5 years in 1 study; it appeared in 6–12 months' use in another. **7.** Carbohydrate & lipid metabolism—Decreased glucose tolerance occurs in a significant number of users: carefully observe diabetic and prediabetic patients. Triglycerides and total phospholipids may increase. **8.** Elevated blood pressure (BP) occurs in some users in a few months, and degree may relate to progestogen dose. Hypertension prevalence in users is no higher than in nonusers in the first year, but increases with longer exposure; in the 5th year it is 2½–3 times the first year. Age is strongly correlated with hypertension in users. Those with history of elevated BP (hypertension), pre-existing renal disease, history of toxemia or elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during menstrual cycles may be more likely to develop elevated BP on OCs and thus should be monitored closely. Even though elevated BP may be in the "normal" range, do not ignore clinical implications. Follow closely, particularly those with other risk factors for cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** Headache—Onset or exacerbation of migraine or development of headache of a new pattern that is recurrent, persistent or severe requires stopping OCs and evaluating cause. **10.** Bleeding irregularities—Breakthrough bleeding (BTB), spotting and amenorrhea are frequent reasons for discontinuing. In BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to a higher estrogen OC only when necessary as this may increase thromboembolic risk. Those with a history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patients with postpill amenorrhea when galactorrhea was present. **11.** Ectopics—In failures with combination OCs, the ratio of ectopic to intrauterine pregnancies is no higher than in nonusers. There may be an increased risk of ectopics after discontinuing. **12.** Breast feeding—OCs may decrease quantity and quality of milk. A small fraction of OC steroids appears in milk. Effects if any on the child are unknown. If feasible defer OCs until after weaning. **13.** Infertility may occur in women discontinuing OCs, which appears independent of duration of use. While impairment diminishes with time, there is still an appreciable difference in nulliparous but not parous women after 30 months; difference is negligible after 42 months.

Precautions—Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen and pelvis, with BP, pap and lab tests. Pre-existing uterine leiomyomata may enlarge. Mental depression may occur; with positive history, observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma, or cardiac, hepatic or renal dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observe carefully and discontinue if jaundice occurs. Steroids may be poorly metabolized in liver dysfunction and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblastic anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T^4); decreased T^3 uptake, unaltered free T^4; decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceride, phospholipid; reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged OC use on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response is not established. OCs may mask onset of climacteric. Information for patients—see patient labeling. Drug interactions—OC effectiveness may be decreased and more BTB occur with rifampicin, isoniazid, ampicillin, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of drugs such as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensives, vitamins, hypoglycemics.

Adverse Reactions—Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis and thrombosis; pulmonary embolism; myocardial infarction and coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding; congenital abnormalities. There is evidence of association between the following conditions and OCs, though confirmatory studies have not been done: mesenteric thrombosis; Budd-Chiari syndrome, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following have been reported with OCs and are believed drug related: nausea, vomiting, gastrointestinal symptoms, breakthrough bleeding, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargement, secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. The following have been reported and association has not been confirmed or refuted: premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, itching, vaginitis, porphyria, impaired renal function, anemia, pancreatitis, hepatitis, colitis, gingivitis, lupus erythematosus, rheumatoid arthritis, pituitary tumors (e.g., adenoma) with amenorrhea and/or galactorrhea after use, endometrial, cervical and breast carcinoma.

Acute overdosage—Serious ill effects have not been reported after large acute doses of OCs in young children, but nausea and withdrawal bleeding might occur.

Important note—Full prescribing information should be consulted prior to use and is available on request.

Demulen® Each white tablet contains ethynodiol diacetate 1 mg. and ethinyl estradiol 50 mcg. Each pink tablet in Demulen-28® is a placebo containing no active ingredients.

A MR. GOODWRENCH SAFETY TIP:

"Wherever you go, your baby should have a special baby sitter."

LOVE SEATS The General Motors infant and child Love Seats were designed, tested and approved by GM professional safety engineers who are specialists in restraint systems. They worked in conjunction with medical authorities, pediatricians and child health experts.

Love Seats are built to GM quality standards. Made with tough, automotive-type polypropylene—with a harness of genuine automotive-type webbing. Lined with a comfortable foam padding that is sanitary, easy-to-clean, reversible.

GM Love Seats are flame resistant, scuff resistant, and resist cracking in cold weather. Yet, strong and durable as they are, Love Seats are surprisingly lightweight, easy-to-carry, handy-to-store.

Our Love Seats come in two models:

The Infant Love Seat is for infants from birth to 20 pounds. Rearward facing. Semi-reclining. Can also be used as a carrier, sleeper or feeder.

The Child Love Seat is for babies 20 to 40 pounds, up to 40" tall, who can sit up by themselves. Special five-point safety harness. Lets your child sit facing forward at window viewing height.

Infant and Child Love Seats are available through your General Motors dealer. See him to get the right Love Seat for your baby. Today.

KEEP THAT GREAT GM FEELING WITH GENUINE GM PARTS.

SOUTHERN MEDICAL ASSOCIATION DIAL access

the ModiCon balance

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in the 28-day regimen contains inert ingredients.

TRADEMARK

low hormonal content/high patient acceptability

Low hormonal content, yet highly effective
ModiCon combines a low dose of estrogen (0.035 mg ethinyl estradiol) with a low dose of progestin (0.5 mg norethindrone). In clinical trials, the pregnancy rate in **1,168** patients completing **16,345** cycles was only **0.22** per 100 woman-years.

Good patient acceptability with low incidence of amenorrhea and good cycle control†
With ModiCon, the majority of women who start with it stay with it.

Throughout clinical trials, the total incidence of amenorrhea was only **1.0%**. The average cycle dropout rate during the first three months because of menstrual disorders was only **1.2%**.

ModiCon is available in both 21 and 28-day regimens in the unique DIALPAK* Tablet Dispenser.

See the complete Prescribing Information for this product, a summary of which is on the next page.

ModiCon

†Serious as well as minor side effects have been reported with the use of oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be fully aware of the complete Prescribing Information for this product.

ORTHO

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information and patient information before prescribing the product.

INDICATION: CONTRACEPTION. The pregnancy rate in women using conventional combination oral contraceptives (containing 35 mcg or more of ethinyl estradiol or 50 mcg or more of mestranol) is generally reported as less than one pregnancy per 100 woman-years of use. Slightly higher rates (somewhat more than one pregnancy per 100 woman-years of use) are reported for some combination products containing 35 mcg or less of ethinyl estradiol, and rates on the order of three pregnancies per 100 woman-years are reported for the progestogen-only oral contraceptives. Table 1 gives ranges of pregnancy rates reported in the literature for other means of contraception. The efficacy of these means of contraception (except the IUD) depends upon the degree of adherence to the method.

Table 1: Pregnancies Per 100 Women-Years. IUD, less than 1-6; Diaphragm with spermicidal product (creams or jellies), 2-20; Condom, 3-36; Aerosol foams, 2-29; Jellies and creams, 4-36; Periodic abstinence (rhythm) all types, less than 1-47; 1. Calendar method, 14-47; 2. Temperature method, 1-20; 3. Temperature method—intercourse only in postovulatory phase, less than 1-7; 4. Mucus method, 1-25; No contraception, 60-80. **DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES:** Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Known or suspected pregnancy (see WARNINGS, No. 5).

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION: An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10-to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000); the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory diseases may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of oral contraceptives) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The findings of this analysis are shown in Figure 1 below. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. Based on the data currently available, the following chart gives a gross estimate of the risk of death from circulatory disorders associated with the use of oral contraceptives:

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS—RISK ASSOCIATED WITH USE OF ORAL CONTRACEPTIVES

Age	Below 30	30-39	40+	
Heavy smokers	C	B	A	A—Use associated with very high risk.
Light smokers	D	C	B	B—Use associated with high risk.
Nonsmokers (no predisposing conditions)	D	C,D	C	C—Use associated with moderate risk.
Nonsmokers (other predisposing conditions)	C	C,B	B,A	D—Use associated with low risk.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception.

4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. (ORTHO-NOVUM 1/50□21 and ORTHO-NOVUM 1/50□28 contain tartrazine. Allergic reactions have been reported with the ingestion of this dye in some patients.) **ACUTE OVERDOSE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Information for authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

All articles published in this JOURNAL must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority.

Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article. They should include name of author(s), article title, name of periodical, volume, page, and year. Name of periodical should conform to that shown in latest *List of Journals Indexed in Index Medicus*. For reference style see current issue of JOURNAL. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2*, Current Investigation and Clinical Opinion, limited to *6*, and Current Developments, for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. **Do not send original art work, x-ray films, or ECG tracings.** Glossy print photographs are preferred, for good black and white contrast is essential.

Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the JOURNAL but may be submitted for paid advertisements, if desired.

Letters to the Editors. A brief Letter to the Editors commenting upon some article which has appeared in the JOURNAL will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

Estradiol...the only estrogen necessary in estrogen replacement therapy

ESTRACE®
(ESTRADIOL)

1-mg. and 2-mg. scored tablets

Estradiol, the active estrogen at the cellular level

Estradiol is the primary estrogen of the human ovary—estrone and estriol are considered its oxygenated metabolites[1]—and the major estrogen secreted during the reproductive life of the woman.[2]

Estradiol, not estrone, is the logical estrogen to replace

At menopause the normal cyclical production of estradiol declines, resulting for many women in the unpleasant symptoms of estrogen deficiency—hot flushes and atrophic vaginitis being the most common. ESTRACE provides the estradiol the ovary produced in the premenopausal years.

ESTRACE...the orally effective estradiol

Estradiol was long thought desirable in oral estrogen replacement therapy, but administration was not practical owing to erratic absorption. With the technique of micronization, dependable oral absorption has been demonstrated.[3,4]

ESTRACE is rapidly absorbed, active at the cellular level, and follows the normal metabolic pathways in its utilization by the body. ESTRACE provides objective[4] and clinical evidence[3] of ready availability and biologic activity because estradiol can be assayed in plasma.

Easy to titrate to lowest effective dosage

ESTRACE is easy to titrate up or down as necessary for the individual patient to arrive at the lowest effective dose as soon as possible. Available in 1-mg. and 2-mg. *scored* tablets, ESTRACE is usually effective in a single dose of 2 mg. per day, administered on a cyclic basis.

ESTRACE® (ESTRADIOL)

Estradiol...the only estrogen necessary in estrogen replacement therapy

1-mg. and 2-mg. scored tablets

Warning

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods.[1-3] This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.[4] The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment[1] and on estrogen dose.[3] In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration;[3] it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY. The use of female sex hormones, both estrogens and progestagens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare.[5,6] This risk has been estimated as not greater than 4 per 1000 exposures.[7] Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis,[8-12] epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects.[13-16] One case control study[16] estimated a 4.7-fold increased risk of limb reduction defects in infants exposed *in utero* to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestagens are effective for these uses. If Estrace® is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation.

Clinical Pharmacology — 17β-Estradiol is the most potent physiologic estrogen and, in fact, is the major estrogenic hormone secreted by the human. Estradiol in Estrace® has been micronized and demonstrated to be rapidly and effectively absorbed from the gastrointestinal tract.[17]

Indications: Estrace® is indicated in the treatment of: 1. Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.) 2. Atrophic vaginitis. 3. Kraurosis vulvae. 4. Female hypogonadism. 5. Female castration. 6. Primary ovarian failure. ESTRACE® HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Contraindications: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients with progressing inoperable or radiation resistant disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (See Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

Warnings: There is now evidence that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.) At the present time there is no evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. However, women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms should be administered an estrogen with caution and a careful breast examination should be performed. A recent study has reported a 2 to 3-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens.[18] An increased risk of post-surgery thromboembolic complications has been reported in users of oral contraceptives.[19,20] If feasible, estrogen should be discontinued at least 4 weeks before, and not resumed until at least 4 weeks after, surgery of the type associated with an increased risk of thromboembolism. Estrogens should not be used in persons with thromboembolic disorders and they should not be used (except in treatment of malignancy) in persons with a history of such disorders in association with estrogen use or in patients with cerebral vascular or coronary artery disease. Benign hepatic adenoma should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepato-cellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives.[21] The relationship of this malignancy to these drugs is not known at this time. There is now evidence that elevated blood pressure occurs with use of estrogens in the menopause[22] and blood pressure should be monitored with estrogen use, especially if high doses are used. Diabetic patients taking estrogens should be carefully observed for decrease in glucose tolerance. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

Precautions: A complete pretreatment and periodic physical examination should be given to estrogen users with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. Conditions which might be influenced by fluid retention such as epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Patients with a history of depression should be carefully observed. Preexisting uterine fibromyomata may increase in size while using estrogen. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be administered with caution in patients with impaired liver function. Estrogens should be used with caution in patients with metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency. Estrogens should be used judiciously in young patients in whom bone growth is not complete. The following endocrine and liver function tests may be affected with larger doses of estrogen: a. Increased sulfobromophthalein retention; b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability; c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered; d. Impaired glucose tolerance; e. Decreased pregnanediol excretion; f. Reduced response to metyrapone test; g. Reduced serum folate concentration; h. Increased serum triglyceride and phospholipid concentration. As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

Adverse Reactions: The following additional adverse reactions have been reported with estrogenic therapy, including oral contraceptives: Breakthrough bleeding, spotting, change in menstrual flow; Dysmenorrhea; Premenstrual-like syndrome; Amenorrhea during and after treatment; Increase in size of uterine fibromyomata; Vaginal candidiasis; Change in cervical eversion and in degree of cervical secretion; Cystitis-like syndrome; Tenderness, enlargement, secretion of the breasts; Nausea, vomiting; Abdominal cramps, bloating; Cholestatic jaundice; Chloasma or melasma which may persist when drug is discontinued; Erythema multiforme; Erythema nodosum; Hemorrhagic eruption; Loss of scalp hair; Hirsutism; Steepening of corneal curvature; Intolerance to contact lenses; Headache, migraine, dizziness; Mental depression; Chorea; Increase or decrease in weight; Reduced carbohydrate tolerance; Aggravation of porphyria; Edema; Changes in libido.

Overdosage: Serious ill effects have not been reported following the ingestion of large doses of estrogen-containing oral contraceptives by young children. Overdosage of estrogen may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration: 1. *Given cyclically for short term use only:* For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause. The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (e.g., 3 weeks on and 1 week off). Attempts to discontinue or taper medication should be made at 3 to 6 month intervals. The usual initial dosage range is 1 or 2 mg. daily of micronized estradiol adjusted as necessary to control presenting symptoms. The minimal effective dose for maintenanace therapy should be determined by titration.

2. *Given cyclically:* Female hypogonadism; female castration; primary ovarian failure. Treatment is usually initiated with a dose of 1 or 2 mg. daily of micronized estradiol, adjusted as necessary to control presenting symptoms; the minimal effective dose for maintenance therapy should be determined by titration.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

"Nonspecific" vaginitis is often masked

"Nonspecific" vaginitis

...Often masked by previsit and routine douches, candidiasis and trichomoniasis.[1]

...Often chronic—in a recent clinical study of 5,000 consecutive cases of chronic vaginitis, the chief cause was undiagnosed H. vaginalis vaginitis, followed by candidiasis and trichomoniasis.[1]

1. Fleury, F.J.: Obstet. Gynecol. News 12:1,25, Aug. 15, 1977.
2. Gardner, H.L., and Kaufman, R.H.: Benign Diseases of the Vulva and Vagina, St. Louis, The C.V. Mosby Company, 1969, p. 191.

When you unmask "nonspecific" vaginitis you may find H. vaginalis

Sultrin
TRADEMARK

Triple Sulfa Cream/Vaginal Tablets

effective against H.vaginalis— the cause of over 90% of "nonspecific" vaginitis[2]

Effective
Based on a review by the National Academy of Sciences/National Research Council, SULTRIN was rated as "effective" against *H. vaginalis.*

Prompt symptomatic relief
Patients can experience relief of embarrassing itching and malodorous discharge. Within the same time, most patients can also achieve marked clinical improvement.

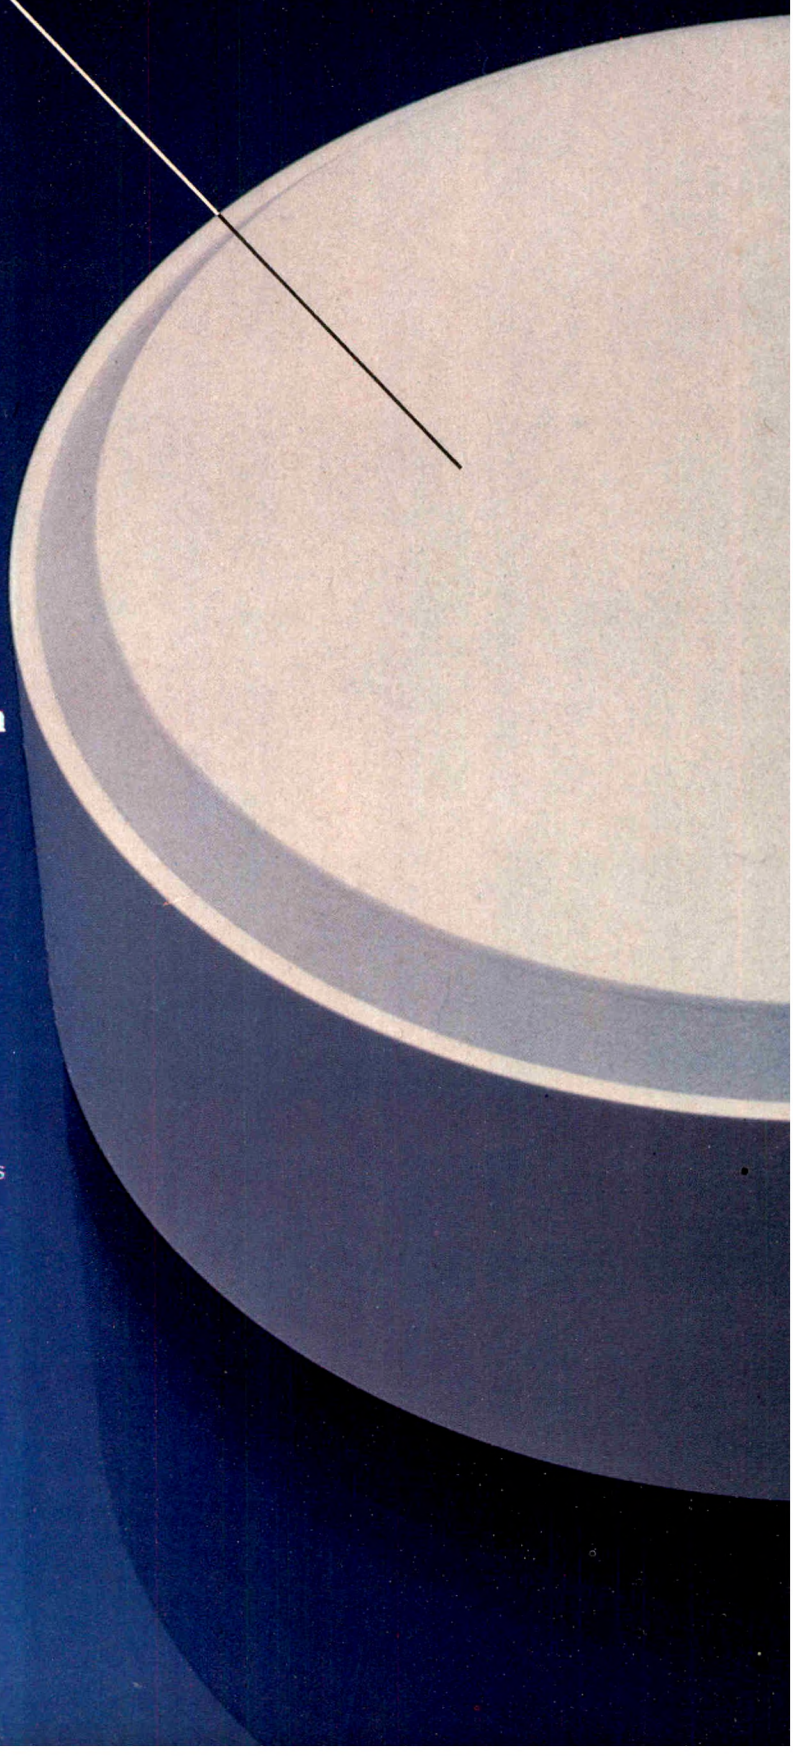
Versatile adjunct in other vaginitides
SULTRIN is also effective in treating H.V. vaginitis concomitant with trichomoniasis and candidiasis.

Convenient choice of dosage forms
SULTRIN comes as a soothing, nonstaining and esthetically pleasing cream or convenient vaginal tablets.

Composition: SULTRIN Cream contains sulfathiazole 3.42%, sulfacetamide 2.86%, sulfabenzamide 3.7%, and urea 0.64%. Each SULTRIN Tablet contains sulfathiazole 172.5 mg, sulfacetamide 143.75 mg, and sulfabenzamide 184.0 mg.

Indications: SULTRIN Cream and Tablets are indicated for treatment of *Haemophilus vaginalis* vaginitis. They may also be used as a deodorant for saprophytic infection following radiation therapy.

Contraindications: Sulfonamide sensitivity and kidney disease.



Dosage: SULTRIN Cream: One applicatorful intravaginally twice daily for 4 to 6 days. The dosage may then be reduced one-half to one-quarter.
SULTRIN Tablets: One tablet intravaginally before retiring and again in the morning for ten days. This course may be repeated if necessary.

Supplied: SULTRIN Cream is available in 2.75 oz. (78 g) tubes with the ORTHO* Measured-Dose Applicator.
SULTRIN Tablets are available in packages of 20 foil-wrapped tablets with vaginal applicator.

The progestogen in oral contraceptives:
But certainly

Norgestrel, the progestogen that distinguishes Ovral and Lo/Ovral.

Today, many physicians are concerned about choosing a suitable estrogen level for their oral contraceptive patients.

The effects of any combination oral contraceptive, however, are largely the result of the synergistic activity between estrogen and progestogen. So it seems wise to choose the progestogen carefully, too.

Norgestrel, the progestogen in Ovral and Lo/Ovral, has many properties worth examining.

Distinctive because it is non-estrogenic and does not add estrogen. Unlike other progestogens in current use, norgestrel has been shown in biological assays to be free from inherent estrogenicity and does not convert to estrogen *in vivo*. So the delicate estrogen-progestogen balance in Ovral and Lo/Ovral remains undisturbed.

It helps maintain a sound endometrium in combination with ethinyl estradiol. Even at very low doses, norgestrel demonstrates a pronounced ability to help support the integrity of the endometrium—a primary function of progestogen in oral contraceptives.

A highly effective estrogen antagonist. Norgestrel displays marked anti-estrogenic activity at the cervical level. It thickens the cervical mucus during the 3-week cycle of therapy and may therefore act as a secondary contraceptive mechanism.

Norgestrel and ethinyl estradiol: together they usually mean patient confidence, comfort and compliance. In separate clinical trials, overall effectiveness with Ovral over an 8 year period was 99.3 percent; with Lo/Ovral over a 4 year period, 99.7 percent.[1] Both Ovral and Lo/Ovral also offered excellent cycle control and a minimum of common side effects.* The drop-out rate due to breakthrough bleeding for Ovral was only 0.5 percent; for Lo/Ovral, only 1.4 percent.

50 mcg Ovral® and 30 mcg Lo/Ovral®: distinguished by norgestrel.

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. The physician should remain alert to their earliest manifestations and in the event of serious adverse reactions, should avoid any oral contraceptives. Contraindications, Warnings, Precautions, Adverse Reactions, etc. in the accompanying IN BRIEF should be carefully considered.

1. Based on life table method.

See important information on following page.

Wyeth Laboratories
Philadelphia, Pa. 19101

OVRAL®
Each tablet contains 0.5 mg norgestrel with 0.05 mg ethinyl estradiol.

LO/OVRAL®
Each tablet contains 0.3 mg norgestrel with 0.03 mg ethinyl estradiol.

Copyright© 1979, Wyeth Laboratories Div. of AHPC, N.Y., N.Y. All rights reserved.

IN BRIEF:

Indications and Usage—OVRAL® and LO/OVRAL® are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5).

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gall bladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well-established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use, and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group.

Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g. thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially cigarette smoking.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well-documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increase in triglycerides and total phospholipids has been observed in patients on OC's; clinical significance of this finding remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease.

Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination.

2. Under influence of estrogen-progestogen preparations, pre-existing uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when relevant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin.

Carcinogenesis—See Warnings on carcinogenic potential of OC's.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses.

The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

OBSTETRICS

Evaluating student performance in an obstetrics and gynecology clerkship

MORTON A. STENCHEVER, M.D.
BRIAN O'TOOLE, PH.D.
DAVID IRBY, PH.D.
Seattle, Washington

The development of a comprehensive evaluation system for an obstetrics and gynecology clerkship at the University of Utah is described and the results of two years experience using it are presented. Seven different measurement procedures were developed and used with 111 junior medical students including pre- and post-tests, oral examination, clinical performance ratings by residents, and ratings by faculty on oral and written presentations and participation in tutorial sessions. Learning gains as measured by pre-post test scores were significant at the 0.001 level. Only six of 37 correlations among the evaluation measures were significantly related at the 0.01 level; furthermore, little relationship could be found between measures of student achievement in cognitive as compared to clinical skill areas. The need for multiple sources of information on student performance in clerkships is discussed (AM. J. OBSTET. GYNECOL. 134:235, 1979.)

DURING clinical clerkships, medical students are expected to apply a broad fund of knowledge to specific problems of patients, to interact skillfully with them, and to master basic technical skills. This integration of knowledge, skills, and attitudes about patient care occurs in a variety of clinical and classroom settings under the tutelage of numerous different personnel (e.g., attendings, house staff, nurses, social workers, etc.). Under such circumstances, accurate appraisal of student competence is both complex and difficult. The question arises: is it necessary to obtain information on student performance from multiple sources? If so, what type of evaluation measures are needed? Some reports of clerkship evaluation systems have described parts of an evaluation program,[1–4] while others have outlined untested general models.[5–6] This paper describes the development and assessment of a comprehensive evaluation system for a junior clerkship in obstetrics and gynecology at the University of Utah. Data on 111 medical students enrolled in this six-week clerkship between September, 1975, and February, 1977, are analyzed to address the following questions:

1. Did students increase their level of knowledge in obstetrics and gynecology during the clerkship?

2. What are the relationships among nine different measures of student performance?
3. What is the relationship between cognitive measures and clinical skill measures of student performance?

Evaluation design

In order to develop an effective clerkship evaluation system, the clerkship curriculum was first analyzed and then revised. In 1970, a modified competence-based curriculum was introduced into the basic obstetrics and gynecology clerkship at the University of Utah. Five areas of competence, a series of learning activities, and evaluation procedures were identified by the faculty.

The clerkship consisted of two three-week rotations at the University Hospital and a community hospital. Learning activities included: ward, clinic, operating room, and delivery room experiences; faculty preceptorships; conferences; grand rounds; self-learning programs; and student presentations.

To evaluate student achievement in the five competency areas, seven different measurement procedures were developed. These included: pre- and post-tests and oral examination, ratings of clinical performance by residents, ratings of an oral and written presentation, and ratings by faculty of student participation in tutorial meetings.

The pre- and post-tests were designed to measure knowledge gains. The tests were identical, consisting of 50 multiple choice questions, and were administered on the first and last days of the clerkship. The oral examination, which evaluated the student's ability to apply knowledge and solve clinical problems, was taken immediately following the post-test. Faculty rated student responses to the oral examination on a four-item rating scale.

Evaluation of student ability to investigate a topic in obstetrics and gynecology and to present the information in a logical and coherent fashion was assessed by faculty using a six-item rating scale. It was completed by faculty for both formal presentations and papers.

Clinical performance on the wards and in other clinical situations was assessed by residents at the end of both three-week rotations. Residents at each hospital (three at the University and three at the community hospital) met as a group and pooled their observations into one rating form for each hospital rotation. The clinical performance form consisted of a 27 item rating scale with general comments.

The didactic teaching sessions focused on case workups and problem solving. Student participation in these sessions was evaluated by faculty using a five-item rating scale. Each student received two evaluations of clinical performance by residents and two evaluations for tutorial sessions by faculty (one from each hospital).

All of these evaluation measures were used to determine the level of student achievement except the pre-test. The percentage contribution of each element to the student's total grade was: 20% post-test, 20% oral examination, 10% paper, 10% presentation, 20% clinical rating by residents, and 20% preceptor rating.

After developing the new curriculum and evaluation models, the entire system was implemented in 1975. Data on student performance in the clerkship from 1975 to 1977 were analyzed using a correlated t test to measure differences between pre- and post-test scores and the Pearson Correlation Coefficient to examine relationships among the seven types of ratings and between measures of cognitive ability and clinical skills.

Results

Pre- and post-tests were administered to determine the degree of knowledge gain during the clerkship. Using a correlated t test to compare pre-test scores (mean = 53.19, SD 7.08) with post-test scores (mean = 76.42, SD 6.49), differences were found which were significant at the 0.001 level.

Seven different evaluation forms were used to assess student achievement in the clerkship. Since two of these forms (clinical performance and preceptor rat-

ings) were completed at both hospitals, nine sources of information were available for analysis. Table I reports Pearson correlation coefficients for the nine measures. Six out of 37 correlations were significant at the $p < 0.01$ level.

The strongest correlations were between resident ratings at University and community hospitals ($r = 0.3389$), between pre- and post-tests ($r = 0.3219$), and between preceptors and residents at University Hospital ($r = 0.2958$). Each of these correlations were significant at the 0.001 level.

Three other correlations were significant at the 0.01 level. These were between resident ratings at the University and student presentations ($r = 0.2889$), between oral exam and resident ratings at the University Hospital ($r = 0.2359$), and between the oral examination and pre-test ($r = 0.2293$).

The association of cognitive ability and clinical skills was examined by dividing the nine evaluative measures into two groups: (1) cognitive measures: pre- and post-tests, oral examination, presentation, and paper; and (2) clinical skills: preceptor and resident ratings at each hospital. The Pearson correlation coefficient between these two sets of measures was low ($r = 0.1539$) and nonsignificant.

Comment

This study was a pilot effort to examine the application of a comprehensive evaluation system to a clinical clerkship. The evaluation program was designed to assess student knowledge, skills, and attitudes through the use of seven different instruments. Analysis of student performance in the clerkship over a two-year period revealed low correlation between the nine measures of student achievement and between cognitive and noncognitive measures. This suggests that high performance in one area of the clerkship (e.g., oral examination) is not necessarily related to high performance in another area (e.g., clinical performance). The strength of this evaluation system is its ability to sample a broad range of student behavior and to balance several performance measures to form the final grade.

Limitations of this evaluation program include the use of identical forms for pre- and post-tests, the expense of employing a large number of measurement procedures, and the lack of demonstrated reliability. The need for a variety of measures is apparent but the number and type of measures are open to debate. While logical arguments were developed as rationale for each measurement procedure, faculty have subsequently determined that writing proficiency was not a critical clerkship objective and, therefore, the paper and its accompanying rating form were deleted.

While costly, a comprehensive evaluation system based on multiple sources of information is necessary in order to accurately evaluate student achievement. In light of increasing pressure for objective evaluation of educational programs and certification of professional competence, further efforts at designing and analyzing clerkship evaluation systems are essential.

A comparison of clindamycin-gentamicin and penicillin-gentamicin in the treatment of post–cesarean section endomyometritis

GERE DIZEREGA, M.D.
LYNN YONEKURA, M.D.
SUBIR ROY, M.D.
ROBERT M. NAKAMURA, PH.D.
WILLIAM J. LEDGER, M.D.
Los Angeles, California

A random comparison of clindamycin-gentamicin (C-G) and penicillin-gentamicin was made in 200 women who developed endomyometritis following cesarean section. All pretreatment profiles indicated similar populations. The clinical response was more favorable in the women receiving clindamycin-gentamicin. The implications of these results upon clinical practice is discussed. (AM. J. OBSTET. GYNECOL. 134:238, 1979.)

THIS STUDY presents a new therapeutic approach to post–cesarean section endomyometritis, the most serious problem of hospital-acquired infection for the obstetrician-gynecologist. Recently, the most popular focus of interest has been preventive antibiotics. Although the strategy of prophylaxis reduces febrile morbidity, it has not avoided the development of serious infections. A widely used alternative approach has been to employ penicillin and an aminoglycoside for the treatment of infected patients, reserving agents effective against *Bacteroides fragilis* for those women who remained febrile. The present study compared this commonly used regimen to clindamycin-gentamicin, which provides superior coverage of *Bacteroides fragilis*. This study design avoids prophylaxis for all patients undergoing cesarean section, restricting antibiotic usage to those patients with infection.

Material and methods

Between February, 1976, and October, 1977, all women undergoing cesarean section at the Los Angeles County–University of Southern California (LAC-USC) Medical Center were eligible for the study. Prophylactic antibiotics for cesarean section were not employed. Women who had a clinical diagnosis of postpartum uterine infection based upon the presence of fever and uterine tenderness received on a random basis, either

penicillin-gentamicin or clindamycin-gentamicin. Five million units of penicillin was administered intravenously every six hours. Also 600 mg of clindamycin was given intravenously at 6 hour intervals. Gentamicin, 80 mg, was given intravenously at 8 hour intervals. In a few instances, the gentamicin dosage was 60 mg and occasionally the route of administration was intramuscular. In most cases, an oral form of penicillin or clindamycin was given after the patient had been afebrile for 24 to 48 hours to complete 10 days' treatment. The gentamicin was continued for the length of hospitalization. In the patients who failed to respond to initial therapy, by a continued febrile course, therapeutic decisions to prescribe additional antibiotics or heparin or perform a second operation were made by the physician team. There were a number of patient exclusions. Patients allergic to penicillin or those who received antibiotics during labor or in the recovery room were not entered into the study. Those patients started on the protocol who were subsequently found to have a urine bacterial colony count of greater than 100,000/cc from the specimen obtained prior to therapy were excluded to avoid the possibility of evaluating a patient whose primary site of infection might be the urinary tract. In addition, there were wide variations in the number of women recruited for the study, depending upon the interest of the senior resident responsible for the service. The majority of patients were enrolled in the study when one of the first two authors rotated through the obstetric service.

Before therapy, blood, urine, and endometrial cultures taken through the cervix were obtained. No attempt was made to utilize a sheathed system for the endometrial specimen and neither special gassed tube nor anaerobic jar inoculation was performed. Tests of renal and liver function were obtained prior to and during therapy.

A number of evaluations were performed to assess the patient's response to therapy. The two populations were analyzed to see if similar risk factors existed prior to treatment. The clinical response was assessed after 6 weeks or more had elapsed to determine the number of women who required additional antibiotics, heparin, or operative care before a cure was achieved. A fever index, a quantitative measure in degree hours of the patient's response to therapy, was measured in all of the study population.

Results

The indications for cesarean section of the two populations are listed in Table I. There were no significant differences noted between the two groups.

The pretreatment patient profile and risk factors of the two populations are listed in Table II. The documentation of the length of labor was too incomplete to permit analysis. Membranes were ruptured for a longer interval in the penicillin-gentamicin group than in the clindamycin-gentamicin group. Although there is a difference, it is not statistically significant. In addition, Fig. 1 demonstrates no correlation between the length of time of membrane rupture and severity of infection as noted by a fever index.

Bacterial isolates were obtained in 48 patients from blood cultures. In the case of isolates considered contaminants, both culture bottles had to have a positive growth.[1] In 29 of the 48 episodes (60.4%), anaerobes

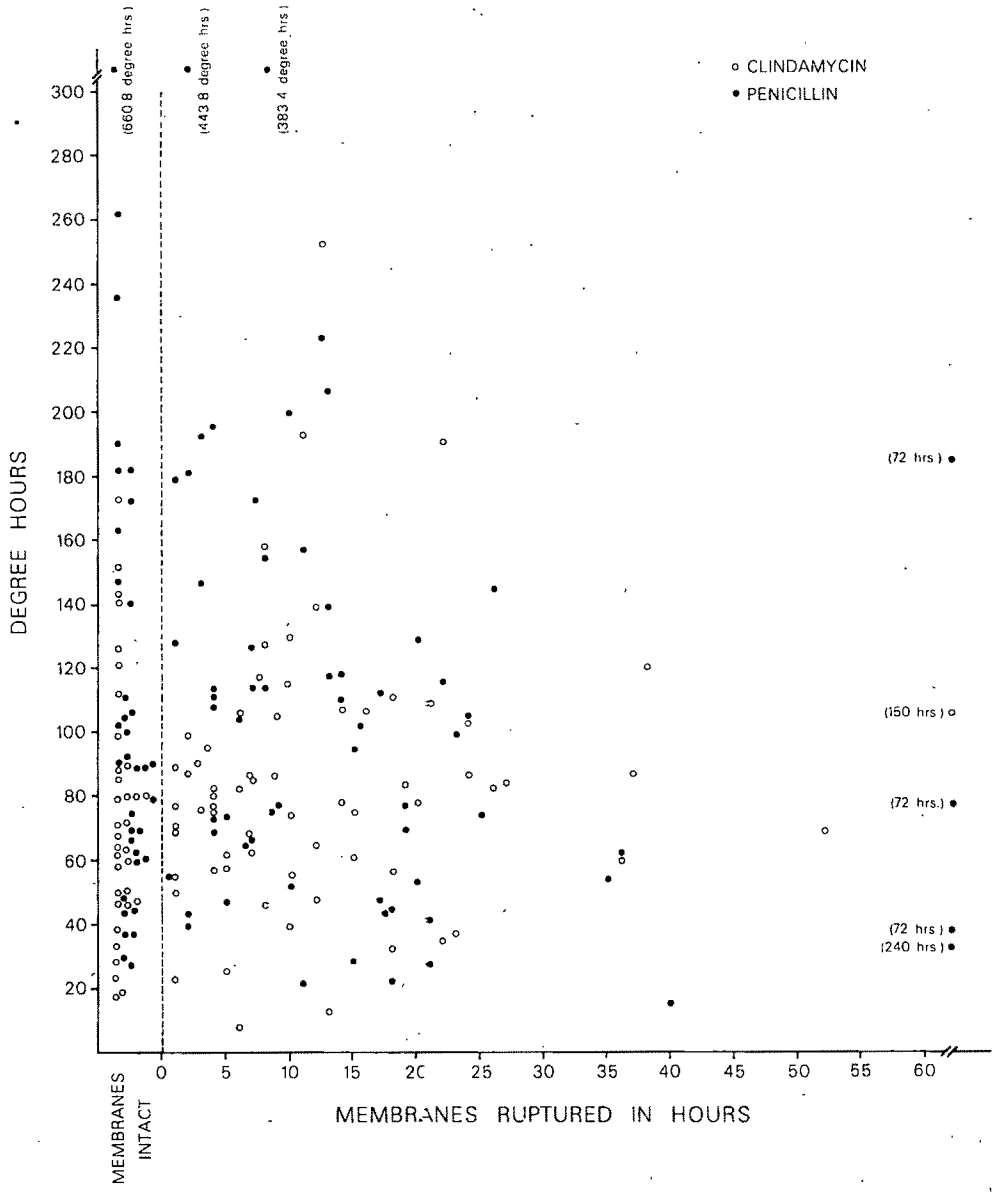

Fig. 1. A scattergram of the patient's febrile response compared to the length of time of membrane rupture.

were isolated. Twelve of the episodes, five with penicillin-gentamicin and seven with clindamycin-gentamicin, involved only the organisms diphtheroids and *Propionibacterium acnes* and may have been contaminants.

The clinical response to therapy is noted in Table III. Most of the evaluations favor the clindamycin-gentamicin regimen. There were fewer problems in this population of women throughout the analysis with statistical significance as noted in Table III.

Comment

The response to clindamycin-gentamicin therapy of post–cesarean section infection was superior to the more commonly employed penicillin-aminoglycoside regimen. This difference is not related to the selection of different patient populations as measured by the indications for cesarean section (see Table I) or pretreatment risk factors (see Table II). We were concerned about the similarity of the two populations when we first viewed the data on the length of time of membrane rupture for we were aware that the frequency of maternal infection increases with the duration of membrane rupture.[2] However, statistical analysis revealed no difference in the two populations. More important, no correlation in this study could be found between the duration of membrane rupture and the

Table III. Comparison of the two regimens

N.S. = Not significant.
*Drug continued, rash disappeared, one patient.
†Drug continued, hematuria stopped.

severity of infection following cesarean section (see Fig. 1). There was a better clinical response in the women who received clindamycin (see Table III). Fewer women required a third antibiotic, fewer serious wound infections developed, and no patient had a dehiscence or required heparin or a second operation.

This therapeutic combination regimen offers clear advantages over the reported prophylactic antibiotic regimens. Although febrile morbidity has been reduced with preventive antibiotics, serious postoperative pelvic infections have still been reported. In this study, the treatment of symptomatic women with clindamycin-gentamicin prevented the progression to serious infection. Whether this result will always be seen will be determined by more observations on a larger number of patients. This regimen avoids the administration of potent antibiotics to all women undergoing cesarean section as well as to the fetus in utero if the antimicrobial drugs are given preoperatively.

Since the results of this study differ from a prior comparison of these two antibiotic regimens,[3] some comment is necessary. There is a striking difference in the patient population of the two studies. In the current evaluation, all patients were seen early in the course of the disease. In the earlier study, some patients had more advanced disease when they were enrolled in the comparison.

The population of women who develop an infection following cesarean section has parallels with the animal model of infection developed by Weinstein and associates.[4] Serious pelvic infection manifested by early-onset sepsis or late-onset abscess formation can occur after the initiating event of a cesarean section in an operative field contaminated by bacteria. The timing of antibiotic administration seems critical. If there is a delay in the use of antibiotics that are particularly effective against anaerobes, serious late infectious complications occur in the human and the rat.

The risk-benefit ratio of the clindamycin-gentamicin regimen has not been established. The majority of the patients treated with penicillin-gentamicin had uncomplicated courses, and the results are remarkably similar to those reported by Gibbs and associates[5] in which serious problems were seen in only 4% of those originally treated with a combination of penicillin-kanamycin. However, serious problems occurred in a few patients who received this combination initially and these were not seen in the clindamycin-gentamicin group. In the current study, there was little toxicity associated with the use of clindamycin. The drug was discontinued in only three patients receiving the initial regimen, one for a rash and in two instances for diarrhea. There were no cases of pseudomembranous enterocolitis. In other geographic locations with different patient populations, more frequent diarrhea or enterocolitis might negate the apparent therapeutic benefit of this combination regimen. Continued experience with this regimen should clarify this point.

Effects of magnesium sulfate treatment on perinatal calcium metabolism

I. Maternal and fetal responses

DWIGHT P. CRUIKSHANK, M.D.
ROY M. PITKIN, M.D.*

Serial maternal and cord blood determinations of the ions and hormones involved in calcium homeostasis were made in pre-eclamptic women treated with intravenous magnesium sulfate. A 4 gm loading dose followed by 1 to 2 gm/hr caused maternal serum magnesium concentrations to rise 150%, to levels of 3.3 to 4.5 mEq/L, and ionized calcium levels to fall 16%, to 1.89 mEq/L. The hypocalcemia evoked a 35% increase in maternal parathyroid hormone concentration without significantly altering calcitonin. Changes in total calcium paralleled those of ionized calcium; phosphorus levels were not affected by magnesium infusion. At the time of delivery the offspring of these women were hypermagnesemic and relatively hypocalcemic, although less so than their mothers. Fetal ionized calcium levels, although lower with magnesium treatment than in control subjects, were within the lower limits of the normal range, which perhaps explains why the fetus did not respond with increased PTH or decreased calcitonin output. These results indicate that the principal maternal response to magnesium-induced hypocalcemia involves increased parathyroid hormone secretion which tends to preserve maternal calcium homeostasis, while the fetus is partially protected from hypermagnesemia and hypocalcemia by the placenta. (AM. J. OBSTET. GYNECOL. 134:243, 1979.)

PARENTERAL magnesium sulfate has been the mainstay of the therapy of pre-eclampsia and eclampsia for many years. Given to prevent maternal seizures, the drug acts principally by antagonizing the action of calcium at the myoneural junction.

Magnesium is intimately involved with calcium homeostasis. Hypermagnesemia depresses serum calcium levels, and some have suggested that this is due to interference with the synthesis or release of parathyroid hormone.[1] Maternal hypocalcemia following therapy with magnesium sulfate has been described.[2] Modest degrees of magnesium deficiency lead to elevations of serum calcium and parathyroid hormone,[3] and more profound hypomagnesemia has been shown to cause hypocalcemia. This too has been postulated as being due to interference with the synthesis or release of parathyroid hormone[4–6] or secondary to magnesium-induced end-organ unresponsiveness.[7]

Magnesium ions cross the placenta[8] and an apparent depression in serum calcium has been reported in fetuses of mothers treated with magnesium sulfate.[9] While some adverse effects on the offspring of these patients have been reported,[10] their occurrence is quite rare.[11]

The purpose of this study was to investigate the effects of intravenous magnesium sulfate therapy on the ions and hormones involved in calcium homeostasis in the mother and fetus.

Materials and methods

Fifteen women with pre-eclampsia were treated with intravenous magnesium sulfate. A loading dose of 4 gm administered over 30 minutes was followed by a maintenance dose of 1 gm (12 patients) or 2 gm (3 patients) per hour. The infusion was continued through labor and for 24 hours after delivery in each patient. The control group consisted of 11 patients (10 normotensive, one hypertensive) infused with dextrose-water or dextrose-saline solutions during abor. Treated and control groups were similar with regard to age (19.2 vs. 21.1 years), parity (0.7 vs. 1.2), duration of gestation (38.9 vs. 38.3 weeks), and mean infant birth weight (3,330 vs. 3,540 grams). The mean interval from entry into the study until delivery was 10 hours (range 4 to 30) in treated subjects and 8 hours (range 2 to 12) in control subjects.

Serum levels of magnesium (Mg), ionized calcium (Ca^{++}), total calcium (Ca), parathyroid hormone (PTH), albumin, and phosphorus (P) and plasma levels of calcitonin (CT) were measured in serial samples of maternal blood and in umbilical arterial (UA) and venous (UV) blood at delivery. The final maternal blood samples in the treated group were obtained 24 hours after cessation of magnesium sulfate therapy, and in the control group 24 hours after delivery.

Baseline samples were collected on all patients and, after the infusion was begun, blood was withdrawn at 15, 30, 60, 120, and 240 minutes, and then every 4 to 6 hours. Blood for determination of Mg, Ca^{++}, Ca, PTH, albumin, and P was collected from an indwelling forearm vein catheter into plain vacuum tubes. UA and UV blood for these determinations was collected by puncture of the vessels in the clamped and cut cord, prior to delivery of the placenta. The blood was allowed to clot at room temperature for 1 hour, and centifuged at 3,000 rpm for 15 minutes. To preserve anaerobic conditions, serum for Ca^{++} determination was withdrawn via needle through the rubber stopper

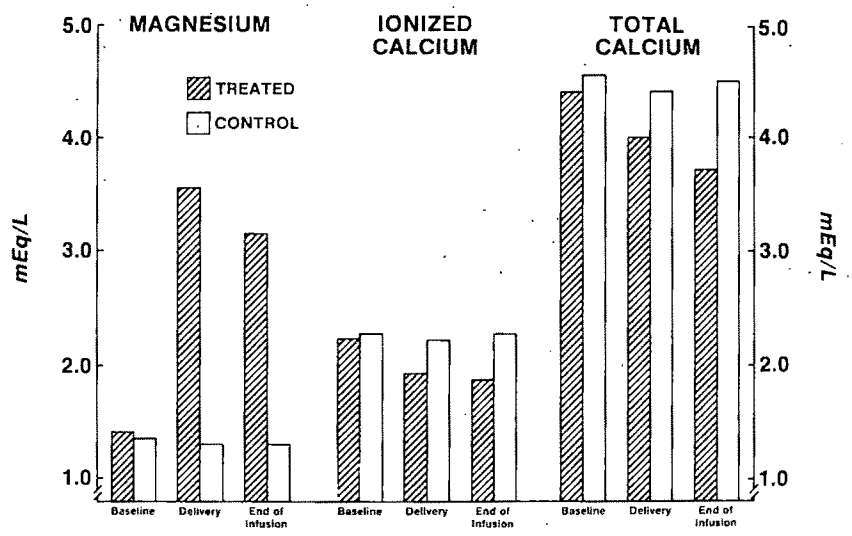

Fig. 1. Mean maternal serum levels of magnesium and ionized and total calcium at baseline, the time of delivery, and the end of the magnesium sulfate infusion.

into a syringe which was immediately capped and sealed. Specimens for determination of Mg, Ca^{++}, Ca, and P were either analyzed immediately or stored frozen for up to 72 hours, previous experiments in our laboratory having demonstrated their stability for at least this period of frozen storage. Serum for PTH determination was frozen, and that for albumin refrigerated, until assayed. Blood for CT determinations was collected into heparinized vacuum tubes, transported to the laboratory in ice, centrifuged in cold immediately, and the plasma separated and frozen until assayed.

Serum Ca^{++} activity was measured on duplicate samples with a calcium flow-through electrode (Orion model 801), Ca and Mg concentrations by atomic absorption spectrophotometry (Perkin-Elmer model 303), and P by the colorimetric method of Fiske and Subbarow.[12] Serum total protein was measured by a modification[13] of the biuret reaction with serum blanks, and the albumin fraction was determined by cellulose acetate electrophoresis (Beckman System R-100 Paper Electrophoresis Analyzer).

Serum PTH was measured by a modification described in detail elsewhere[14] of the RIA method of Arnaud, Teso, and Littledike,[15] utilizing guinea pig antibovine PTH antiserum, purified bovine PTH (Wilson Laboratories, lot 147865) tracer, and dilutions of a pool of human parathyroid tissue culture medium as standards. The assay detects as little as 0.5 microliter-equivalents (μlEq) of standard human parathyroid tissue culture medium per milliliter of serum, and its normal range in adult human beings is 3.76 to 8.56 μlEq/ml.

Plasma CT was measured by a slight modification of the method of Sizemore and associates,[16] with the use of goat antihuman synthetic CT antiserum and human synthetic CT (N.V. Organon, batch SC 30) for tracer and standards. The assay detects as little as 5 pg of CT per milliliter of plasma, and its normal basal range in adult human subjects is 55 to 380 pg/ml.

The assays for both PTH and CT involved measurements at three dilutions of each serum or plasma sample.

Informed consent was obtained from all patients. This project had the prior approval of the Committee on Research Involving Human Subjects.

Results

Maternal.

Magnesium. Baseline values of serum Mg were the same in treated and control patients (Table I). By the time of delivery, mean Mg levels in treated patients were 151% greater than baseline preinfusion values (Table II), rising from 1.42 ± 0.11 to 3.56 ± 0.41 mEq/L, whereas Mg levels in control patients at delivery were unchanged. At the end of the magnesium infusion, the mean Mg level in the treated group was 3.29 ± 0.83 mEq/L, 132% greater than baseline values, whereas control patients 24 hours after delivery had a mean Mg level unchanged from baseline (Fig. 1). Serum Mg levels in treated patients had returned to normal 24 hours after cessation of the magnesium infusion.

The most rapid change in serum Mg levels occurred in the first hour of magnesium sulfate infusion (which included the 4 gm loading dose), during which mean

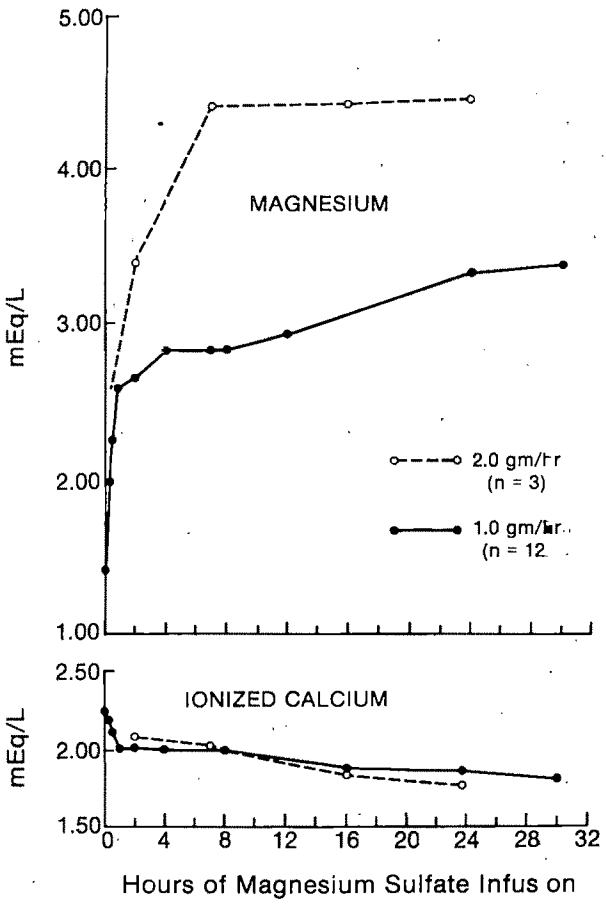

Fig. 2. Mean maternal serum magnesium and ionized calcium concentrations during magnesium sulfate infusions of 1 and 2 gm/hr.

values increased 78%, from 1.42 to 2.57 mEq/L (Fig. 2). During the maintenance dose of 1 gm/hr there was then a more gradual rise to maximum mean levels of 3.33 mEq/L (135% greater than baseline) at 24 hours, after which levels remained relatively constant until the end of the infusion. At a maintenance dose of 2 gm/hr, serum Mg levels rose to a maximum at 6 to 8 hours of 4.47 mEq/L, after which the levels remained fairly constant until the infusion was stopped or the rate of infusion reduced. Thus, with both dosage regimens there was a plateau at which presumably the rate of infusion equalled the rate of excretion, and after this point serum Mg levels did not rise further. This point was reached earlier (6 vs. 24 hours) with the higher (2 gm/hr) infusion rate.

The maximum serum level of Mg achieved was dependent on the *rate* of infusion. At the end of the infusion, there was no statistically significant correlation between either the change in Mg levels vs. the total dose of magnesium sulfate administered ($r = 0.40$) or the change in Mg vs. the hours of infusion ($r = 0.06$). However, the change in Mg levels correlated significantly with the average rate (grams per hour) of infusion ($r = 0.684$, $p < 0.005$).

Ionized calcium. In control subjects, ionized calcium levels remained constant throughout labor, delivery, and the first 24 hours after delivery (Tables I and II). Ca^{++} in magnesium sulfate–treated subjects fell 12.1% by the time of delivery and 15.7% by the end of the infusion (Fig. 1). Both of these changes are highly significant ($p < 0.001$).

As with the rise in serum Mg, the fall in Ca^{++} was most rapid during the first hour of magnesium infusion (Fig. 2), when it fell 11% below baseline values. Following this there was a gradual but continuous decline until the end of the infusion. The percent fall in Ca^{++}, and the absolute levels reached, were the same in patients receiving 1 or 2 gm/hr of magnesium sulfate.

There was no significant correlation between the change in Mg levels and the change in Ca^{++} levels, either at the time of delivery ($r = 0.27$) or at the end of the infusion ($r = 0.32$). However, unlike the situation with serum Mg levels, by the end of the infusion there was significant correlation between the change in serum Ca^{++} and the total dose of magnesium received ($r = 0.65$, $p < 0.01$), and between the change in serum Ca^{++} and the duration of magnesium infusion ($r = 0.51$, $p < 0.05$).

Total calcium. The changes in total calcium paralleled those in ionized calcium in control subjects, in whom there was no significant change from baseline values, and in treated patients, in whom total Ca fell 7.7% ($p < 0.01$) by the time of delivery and 15.0% ($p < 0.001$) by the end of the infusion.

Parathyroid hormone. As indicated in Table I, preinfusion PTH levels in pre-eclamptic subjects were significantly lower than corresponding values in control subjects (4.46 ± 0.81 vs. 5.97 ± 1.16 μlEq/ml, $p < 0.01$). However, in control subjects there was no significant change in PTH levels throughout labor or the early puerperium, whereas PTH levels rose significantly in treated subjects (Table II). Mean PTH levels in treated patients increased 34.9% above baseline by the time of delivery and 31.6% by the end of the infusion, both statistically significant increases ($p < 0.01$). In the three patients infused with 2 gm/hr mean PTH levels increased 54% by the time of delivery. By 24 hours after the end of infusion, PTH levels had returned to baseline values (Table II).

Calcitonin. Plasma CT levels in treated patients fell by an average of 8.0% at the time of delivery and 16.5% by

Albumin (gm/dl)	3.06 ±0.38	3.03 ±0.22	N.S.	3.79 ±0.47	3.54 ±0.48	N.S.	3.89 ±0.41	3.46 ±0.30	$p < 0.05$

the end of the magnesium sulfate infusion, whereas mean CT levels increased somewhat in control patients (Tables I and II). However, there was great variability in the CT response in both treated and control patients, and thus none of the differences in CT concentration between treated and control patients, or among treated patients before and during magnesium infusion, was statistically significant.

Phosphorus. There was no significant change in serum P during magnesium sulfate infusion, nor were there any significant differences between treated and control subjects at any time during the study period (Tables I and II).

Albumin. Baseline serum albumin concentrations were similar in treated (3.13 ± 0.33 gm/dl) and control (3.04 ± 0.23 gm/dl) subjects. Furthermore, at the time of delivery, there was no significant difference in albumin concentrations between treated and control subjects, and there had been no significant change from baseline values within either group (Tables I and II).

However, by the end of the infusion, serum albumin concentration in the treated group had fallen 19.2% ($p < 0.001$), whereas levels in control subjects had fallen 9.2% at 24 hours after delivery ($p < 0.05$).

Maternal-fetal relationships at delivery. Relationships between maternal and umbilical blood studies are shown in Table III. In control subjects, Mg levels in umbilical blood exceeded those in the mother, whereas in treated patients umbilical blood Mg levels, although more than twice as great as control cord blood levels, were lower than those in maternal venous blood. The ratio of fetal to maternal mean Mg levels was 1.07 in control subjects and 0.87 in treated cases, indicating that the transplacental magnesium gradient was reversed with magnesium treatment.

Ionized calcium was 4.2% lower in UV and 6.2% lower in UA in treated than in control subjects, but the depression of Ca^{++} in the fetus was not as great as that in maternal blood of treated subjects.

UV and UA total calcium levels were the same in treated and control subjects, despite the fact that maternal venous Ca levels were 8.4% lower in treated subjects.

PTH levels were lower in the cord blood of treated compared with control subjects, with the difference statistically significant in UV but not in UA.

Calcitonin levels did not differ significantly in treated and control subjects, in either maternal or fetal blood.

Phosphorus levels in fetal blood exceeded those in maternal, in both treated and control subjects. There was, however, no significant difference between treated and control groups in either maternal or fetal phosphorus levels.

Maternal serum albumin concentrations at delivery were essentially identical in treated and control subjects. The fetuses of treated patients had significantly higher albumin concentrations than those of control subjects in UA (but not in UV) serum.

Comment

Maternal response. Maternal serum magnesium levels rise to levels two to three times normal with magnesium sulfate infusions of 1 to 2 gm/hr. With either dosage regimen a plateau is reached, presumably when the rate of infusion equals that of urinary excretion. This plateau occurs at 24 hours (3.33 mEq/L) in patients treated with 1 gm/hr, and much sooner and at a higher level (6 to 8 hours, 4.47 mEq/L) in those receiv-

ing 2 gm/hr. Once the plateau level is reached, the magnesium levels appear to be unaffected by the total dose or duration of treatment, but only by the rate of infusion. This effect is especially obvious in our data by the end of the magnesium sulfate infusion. It is less apparent at delivery, because a number of patients treated with the lower dose had not reached the plateau level by the time of delivery.

This report represents the first systematic study of serum Mg levels with intravenous magnesium sulfate treatment, and it is interesting to note that the values attained with infusions of a 4 gm loading dose followed by 1 gm/hr are slightly below the "therapeutic range" (3.5 to 7 mEq/L) described by Pritchard[17] with intramuscular administration of the drug. The efficiency of the intravenous regimen in preventing seizures suggests that therapeutic levels may not be as high as previously defined for the intramuscular route.

Magnesium treatment clearly depresses maternal ionized calcium levels, and it must be emphasized that the magnitude of the fall in Ca^{++} is indeed remarkable. Serum Ca^{++} is normally regulated within a very narrow range. Pitkin and Gebhardt[18] found normal serum Ca^{++} in late pregnancy to be 2.24 ± 0.06 mEq/L (mean ± S.D.). Assuming the normal range to be described by mean ± 2 S.D., the fall in Ca^{++} caused by magnesium sulfate infusion can be seen to be quite large—the change between baseline and delivery values represents a fall of 4.5 S.D. and that between baseline and the end of the magnesium infusion a fall of nearly 6 S.D. The levels to which Ca^{++} fell correlated directly with the duration of magnesium sulfate treatment and the total dose of magnesium given. A correlation could not be demonstrated, however, between the absolute levels of Mg and Ca^{++} achieved. Most likely, a direct relationship between these two parameters was not found because each is influenced by other variables, serum Mg chiefly by urinary excretion and Ca^{++} mainly by PTH secretion. The modulating effects of PTH on Ca^{++} are probably the reason that the fall in serum Ca^{++} was the same in patients treated with 1 or 2 gm/hr of magnesium sulfate, despite the fact that those treated with 2 gm/hr achieved higher serum Mg levels.

The observed changes in total calcium levels are related to changes in ionized calcium (which accounts for about 50% of total calcium) and in albumin (to which nonionized calcium is bound). In treated patients at delivery, the 12% fall in ionized calcium (induced by magnesium sulfate) accounts for a 6.0% fall in total calcium, whereas the remaining 1.7% fall in total calcium is due to the 2.3% drop in serum albumin. Likewise at the end of the infusion, the 15.7% drop in ionized calcium accounts for a 7.9% fall in total calcium, whereas the remainder is due to the 19.2% fall in serum albumin. The more marked fall in serum albumin in treated patients compared to control subjects is probably due to the intravascular volume contraction of these pre-eclamptic patients at the beginning of infusion and the quantities of intravenous fluid used in therapy, as well as the marked mobilization of extracellular fluid which occurs after delivery.

The mechanism through which hypermagnesemia induces a fall in serum ionized calcium remains unclear, but the significant PTH response demonstrated by treated subjects in this study suggests some mechanism other than suppression of parathyroid gland function, which some have proposed.[1, 19]

PTH levels increased promptly and substantially in association with magnesium-induced falls in serum Ca^{++} concentration, and this increased hormone secretion clearly represents a protective response against even greater degrees of hypocalcemia. While symptomatic maternal hypocalcemia as a complication of magnesium sulfate therapy has been described,[2] its rarity reflects the efficacy of the parathyroid gland in maintaining calcium homeostasis.

CT acts to reduce serum Ca^{++}, and it is interesting to speculate that the observed depression of maternal CT levels in magnesium-treated subjects is a response to the fall in Ca^{++}. Because of the large variation in CT response within both the treated and control groups, however, statistical significance cannot be ascribed to this fall in maternal CT and it seems unlikely that CT is involved in the homeostatic response to hypermagnesemia.

Maternal-fetal relationships. The observed maternal-fetal relationships at delivery indicated a "protective" effect of the placenta in modulating the effects of altered maternal Mg and Ca^{++} on fetal levels. Thus, although cord blood levels of Mg were increased in treated patients, the proportionate increase was not as great in fetal as in maternal blood. Likewise the reduction of fetal serum Ca^{++} was not as great as the fall in maternal levels.

Despite the relative hypocalcemia of the fetuses in the treated group, they did not respond by increasing PTH output, fetal PTH levels in treated patients being lower than in control subjects. This would seem to indicate that the fetal parathyroid is relatively suppressed, similar to the situation which has been described in neonates.[20, 21] However, our finding of cord PTH levels (both control and treated) within the normal adult range speaks against parathyroid suppression and more in favor of a lack of normal adult responsiveness.

Likewise, the fetus did not seem to respond to hypocalcemia by suppressing CT production, fetal CT levels being the same in treated and control subjects.

The apparently higher PTH concentrations in UV than UA of control subjects might give the impression that PTH crosses the placenta, but this is known not to occur.[22–24] However, this difference is more apparent than real, for statistically the difference between control UV and UA PTH levels was not significant ($p > 0.05$).

Human polymorphonuclear leukocyte phagocytosis in pregnancy

Development of inhibition during gestation and recovery in the postpartum period

ROBERT H. PERSELLIN
LINDA L. THOI
San Antonio, Texas

The phagocytosis of *S. aureus* by normal human PMN leukocytes was inhibited by pregnancy serum. Control sera from normal adult nulliparous women, from men, and from cord blood all functioned normally in support of phagocytosis. However, particle ingestion was reduced significantly ($p < 0.001$) when leukocytes were in 15% pregnancy serum obtained at term. To determine at what stage in pregnancy the inhibition of phagocytosis could first be detected, sera were obtained from multiple pregnant donors and pooled according to week of gestation. Significantly fewer bacteria were ingested in each of the serum pools obtained after week 16 of pregnancy and the inhibitory effect persisted through gestation. Following delivery, less inhibition was detected as early as 2 days post partum. Phagocytosis assays were performed in six matched maternal and cord serum pairs. Five of the six maternal sera showed inhibition of phagocytosis; one pregnancy and all cord sera functioned normally in support of bacterial ingestion by normal granulocytes. Since neutrophils are essential to the development of rheumatoid arthritis and certain other inflammatory disorders, the subsidence of these diseases during gestation and their exacerbation post partum could be related, at least in part, to the inhibitory effects of pregnancy serum on leukocyte functions. (AM. J. OBSTET. GYNECOL. 134:250, 1979.)

ALTHOUGH MOST of the observations presented thus far have been retrospective, it is generally accepted that many rheumatic and other inflammatory disorders subside during pregnancy.[1, 2] The exact nature of the factor or factors responsible for this amelioration of disease activity is unknown, but adrenocorticosteroids, estrogenic or progestational hormones, and pregnancy-related serum proteins have all been considered.[1] We have presented evidence that pregnancy serum depresses some of the functions of normal polymorphonuclear (PMN) leukocytes.[3, 4] These alterations of neutrophil functions could provide an explanation for the subsidence of inflammatory processes during gestation. We sought to determine whether the inhibitor of phagocytosis detected in pregnancy paralleled the clinical amelioration of arthritis during gestation and its exacerbation post partum. Sera obtained at various intervals throughout the course of gestation and after delivery were studied for their effects on neutrophil phagocytosis. The results presented in this paper show a close correlation between the effects of pregnancy serum on cellular functions and disease activity and could provide an explanation for remissions of inflammatory disorders during gestation.

tion of 6% dextran-saline. The leukocyte-rich plasma was collected, centrifuged at 270 × g for 15 minutes in the cold, and the white blood cell (WBC) pellet was washed in Hanks' buffer containing 0.01% bovine serum albumin and 150 mg/dl of dextrose. This buffer was used in all experiments. Approximately 75 to 80% of the isolated cells were PMN and more than 95% were viable as determined by trypan blue dye exclusion. Leukocytes from three or more individuals were pooled and cell concentrations were adjusted to 5×10^6 WBC/ml.

Serum pools. Serum was obtained from women with uncomplicated, untreated, intrauterine pregnancy at various intervals throughout gestation and pooled at each 2 to 4 week interval of pregnancy. The pool from women less than 12 weeks pregnant contained only two individual serum samples. Each of the following pools contained three or more individual sera: 12 to 16 weeks, 16 to 18 weeks, 18 to 22 weeks, 22 to 26 weeks, 26 to 30 weeks, 30 to 34 weeks, 34 to 38 weeks, and at delivery. Sera were also obtained following uncomplicated deliveries in unmedicated women at 2 day intervals for the first week post partum and every 2 weeks thereafter until the sixth week. Normal serum pools were prepared from healthy male and from healthy female donors. The normal female serum pool was obtained from nulliparous adults who had never received oral contraceptives. A cord serum pool was obtained from umbilical cord bloods following the second stage of uncomplicated labor. Each pool contained serum from eight or more donors. All experiments utilizing human bloods were approved by the local human experimentation committee. Serum pools were stored at −76° C until studied. Only sterile sera without bactericidal activity for the organism studied were utilized.

Bacteria. A fresh growth of *Staphylococcus aureus* grown on trypticase soy agar was used for phagocytosis studies. Organisms were diluted so that the bacteria : WBC ratio was 5 : 1.

Phagocytosis assay. Into sterile plastic tubes were placed 0.5 ml of the WBC suspension, 0.15 ml of the serum to be studied, and 0.15 ml of buffer. These normal leukocytes were preincubated in the serum at 37° C for 30 minutes with gentle mixing prior to the addition of 0.2 ml of the bacterial suspension. The final serum dilution was 15%. Following rapid mixing with bacteria, tubes were capped, rotated end-over-end at 30 rpm in a 37° C 5% CO_2 water-jacketed incubator, and at various time intervals aliquots were removed for analysis of phagocytosis. Glass slides were smeared and stained and 300 PMN leukocytes per slide were counted. The number of cells clearly containing at least one microorganism was quantitated. Previous studies[3] indicated that 30 minutes of incubation was a representative time for assay and this period was used in the data presented in this paper.

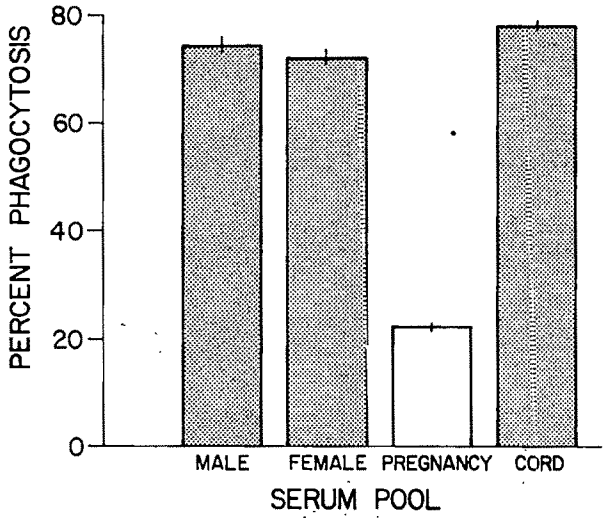

Fig. 1. Effect of various serum pools on the phagocytosis of viable *S. aureus* by normal PMN leukocytes. The pregnancy pool was obtained from eight donors, each 36 to 40 weeks pregnant. All sera were studied at 15% dilution in Hanks' BSS. The percent of neutrophils containing one or more organisms was determined after 30 minutes' incubation. Shown are the means ± 1 S.E.M. for two experiments, each with several replicates. Significantly fewer ($p < 0.001$) normal PMN leukocytes had ingested bacteria in pregnancy serum than in any of the other serum pools studied.

Statistical analysis. Significance was determined with Student's t test. Data are presented as the means ± S.E.M. derived from numerous experiments, each with multiple replicates.

Results

The effect of various human serum pools on the phagocytosis of viable *S. aureus* by normal human neutrophils is shown in Fig. 1. Following preincubation of cells in serum for 30 minutes at 37° C, bacteria were added and phagocytosis was measured after 30 minutes' incubation. Prompt and efficient phagocytosis was supported by the male, the female, and the cord serum pools. In each case in these experiments, over 70% of PMN leukocytes contained ingested bacteria. However, significantly fewer neutrophils contained intracellular microorganisms when the phagocytes were suspended in 15% pregnancy serum ($p < 0.001$). This difference was seen when pregnancy serum was contrasted with either the male, the female, or the cord serum pools. Leukocyte viability was not altered by any of the sera studied, and none was bactericidal.

In separate experiments, individual sera obtained during labor were contrasted with matched umbilical

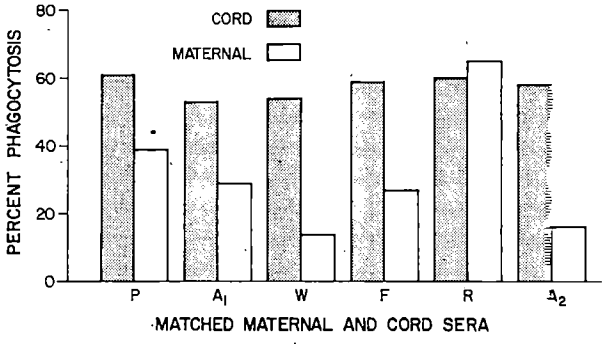

Fig. 2. Phagocytosis of viable *S. aureus* by normal neutrophils in matched pregnancy and cord sera. Serum was obtained from six individuals during labor and from matched umbilical cords after the second stage of labor. Each pair was simultaneously studied at 15% dilution. Time of incubation was 30 minutes.

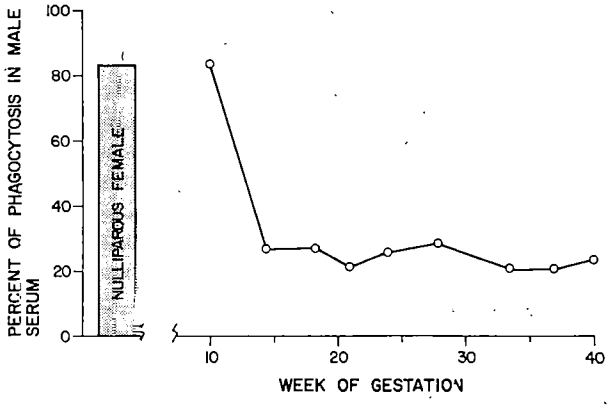

Fig. 3. Effect of sera obtained throughout gestation on the phagocytosis of *S. aureus* by normal human PMN leukocytes. The percentage of normal neutrophils ingesting one or more organisms in 15% male serum was set as 100% activity. The normal female serum pool was obtained from nulliparous females who had never taken oral contraceptives. Sera from multiple pregnant donors were pooled according to week of gestation and studied simultaneously for their effect on *S. aureus* uptake by normal neutrophils. See text for details.

cord sera. The results for six sets of matched sera are shown in Fig. 2. Phagocytosis by normal neutrophils was supported by each of the cord sera. In these experiments over 50% of PMN leukocytes contained one or more organisms. However, in five of the six matched sera studied, there was inhibition of bacterial ingestion by the maternal serum. One pregnancy serum, maternal serum R, did not inhibit phagocytosis. The matched set R was studied a second time and again phagocytosis was normal in both the cord and maternal sera.

To determine at what stage in pregnancy the inhibition of phagocytosis could first be detected, sera were obtained from multiple pregnant donors and pooled according to week of gestation. Phagocytosis in an adult male serum pool was established as the normal control. A serum pool derived from nulliparous women who had never received oral contraceptive medications was simultaneously studied at an identical dilution and served as a second control. In these experiments, the percent of normal PMN leukocytes ingesting microorganisms in the nulliparous female pool was 83% of that in the male serum pool. Serum obtained in the first 16 weeks of gestation did not inhibit phagocytosis. However, significantly fewer bacteria were ingested in each of the serum pools obtained after week 16 of pregnancy, the inhibitory effect persisting from the 16 to 18 week pool throughout gestation (Fig. 3).

After delivery, the inhibition of phagocytosis seen throughout pregnancy rapidly disappeared. Sera obtained from multiple donors at various time intervals post partum showed a return toward normal support of phagocytosis as early as 2 days after delivery (Fig. 4). All sera were contrasted with the effect of a male serum pool. Additional controls were a pregnancy pool obtained between 36 and 40 weeks of gestation and a nulliparous female pool. Thus, serum from pregnancy donors after 16 weeks' gestation inhibits phagocytosis by normal neutrophils. This suppressive effect persists throughout gestation but returns toward normal several days post partum.

Comment

We have previously documented that the phagocytosis of both viable and heat-killed *S. aureus* by normal human neutrophils is significantly diminished in the presence of pregnancy serum.[3, 4] Differential studies involving either leukocytes obtained from pregnant or control subjects, when suspended in either pregnancy or control serum pools, indicated that the inhibition was due to a humoral and not a cellular factor. Intracellular metabolic events occurring after ingestion, including bacterial killing and nitroblue tetrazolium reduction, were decreased in proportion to the number of particles ingested. These findings suggested that the active serum component exerted its inhibitory action at the surface of the PMN leukocyte.[4]

In this paper we present evidence that the inhibitory action of pregnancy serum on neutrophil functions can be detected as early as weeks 16 to 18 of gestation. The serum specimens obtained prior to week 16 supported prompt and efficient ingestion and did not differ from any of the controls studied. Pregnancy serum obtained after 16 weeks, however, suppressed phagocytosis and this inhibitory action persisted throughout the remainder of gestation. Shortly after delivery, postpartum

serum was found to support phagocytosis in a more efficient manner. The marked inhibitory activity detected during pregnancy was greatly diminished as early as 2 days after delivery.

Six pairs of matched maternal and cord sera were studied simultaneously and contrasted with control serum. Five of the six pregnancy sera obtained at the time of delivery contained the inhibitor but, interestingly, one (maternal serum R) did not. This finding suggested that the serum suppressor developed in most but not all pregnancies. In addition, it was apparent that cord serum supported phagocytosis as well as normal adult serum pools, indicating that the inhibitor present during gestation did not cross the placenta.

The nature of the humoral constituent responsible for this suppression of phagocytosis is not yet known with certainty. In previous studies we have shown the inhibitor to be heat stable and nondialyzable.[3] The possible role of hydrocortisone was also investigated. The data obtained indicated that cortisol in the pregnancy serum pool was not responsible for the inhibition of granulocyte functions observed.[4] Hydrocortisone, in vitro, in amounts exceeding by fivefold the concentration in pregnancy serum did not inhibit ingestion. In addition, the level of inhibition of phagocytosis detected in individual pregnancy sera did not correlate with their cortisol concentrations. Previous authors have failed to show an inhibition of phagocytosis by the in vivo administration of steroid.[5, 6] In more recent experiments, we have localized the active inhibitory component to a large-molecular-weight protein fraction isolated with Sephadex G-200 chromatography. Preliminary experiments have suggested that the inhibitor has physical-chemical characteristics resembling the pregnancy zone protein (PZP) described by von Schoultz and Stigbrand[7] and by Straube and coworkers.[8] Further confirmatory experiments must, however, be done.

This demonstration of diminished neutrophil activity during gestation and restoration of normal function post partum closely parallels the course of rheumatoid arthritis and several other inflammatory disorders during pregnancy. The amelioration of inflammatory joint disease is usually apparent in the first trimester in most, but not all, individuals and arthritis recurs by 6 weeks

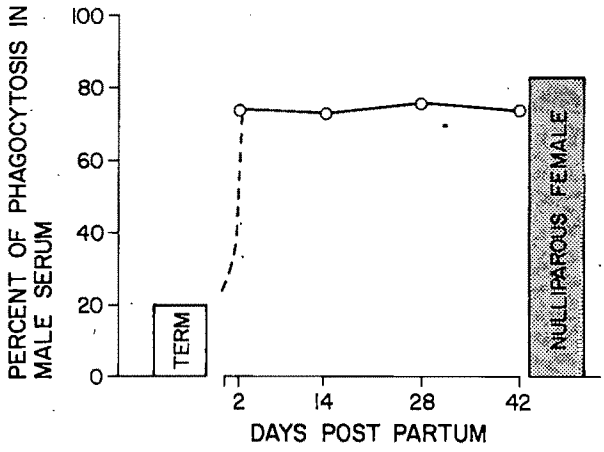

Fig. 4. Disappearance of pregnancy serum inhibition of phagocytosis post partum. Sera were obtained from multiple donors at various time intervals post partum, diluted to 15%, and contrasted with the effect of male serum (100% activity), term pregnancy serum, and nulliparous female serum pools on the ingestion of *S. aureus* by normal human neutrophils.

post partum in 50%.[2] Since neutrophils are essential to the development of synovitis in rheumatoid arthritis, their suppression by pregnancy serum could account for this improvement; the disappearance of the suppressor post partum could then lead to the disease exacerbation usually observed. Thus, the timing of the development of the suppressor closely parallels the clinical observation of rheumatoid arthritis. It is of interest that not all of the sera obtained during pregnancy inhibited phagocytosis. One of the six matched maternal-cord pairs did not suppress bacterial ingestion by normal neutrophils. A further parallel is recognized with rheumatoid arthritis in that only approximately 75% of patients with rheumatoid arthritis will report amelioration of their arthritis during gestation.[1, 2] The ultimate characterization of the neutrophil inhibitor and its quantitation in the serum of patients with rheumatoid arthritis in a prospective manner would provide the essential information required. The final elucidation of the pregnancy regulator would provide additional clues to the mechanisms responsible for the alteration of inflammation during gestation and could suggest new avenues for therapeutic intervention.

The effects of estrone, estradiol-17β, estriol, testosterone, progesterone, and 20α-dihydroprogesterone on incorporation of ^{3}H-thymidine into cultured lymphocytes from normal men and nonpregnant women in response to allogeneic stimulation was investigated with two-way MLR. A dose-dependent reduction in the mean percent incorporation was observed in the range of progesterone concentration between 2×10^3 and 10^4 ng/ml with statistically significant differences from the control cultures. Estradiol-17β at 10^4 ng/ml produced a slight but significant inhibition of incorporation. No significant change in incorporation occurred with the other steroids tested. Since the suppressive property of progesterone in phytohemagglutinin-induced lymphocyte culture reported in our previous communication was reproduced by the present investigation in MLR, the possible role of progesterone in immunoregulation during pregnancy is emphasized as has been postulated previously. (AM. J. OBSTET. GYNECOL. 134:255, 1979.)

IT HAS RECENTLY been reported that progesterone or estra-1,3,5(10)-trienen-3,17β-diol (estradiol-17β) have inhibitory effects on lymphocyte response in vitro to phytohemagglutinin (PHA)[1] or to allogeneic stimulation.[2] However, the physiologic significance of the immunosuppressive property has not yet been established, because the effective concentretions were considerably higher than those in peripheral blood during pregnancy.

We have reported an inhibitory effect of progesterone and 20α-hydroxypregn-4-en-3-one (20α-dihydroprogesterone) on lymphocyte response to PHA and have proposed that progesterone would probably suppress the maternal cell-mediated immunity at the placental site rather than at the systemic level.[3, 4] Following our previous communications, it is the purpose of the present investigation to examine whether or not the suppressive action of the steroids toward lymphocytes is reproducible in the mixed lymphocyte reactions (MLR), a recognized method of testing allograft immune reactions in vitro.

Materials and methods

A total of 58 blood samples were taken from 40 informed healthy men and nonpregnant women who were not taking oral contraceptives. The procedure described previously[4] was followed for preparation of lymphocytes, and the lymphocyte suspension at the final concentration of 1.5×10^6 cells/ml of a mixture of tissue culture medium (RPMI-1640, Flow Laboratories, Inc., Rockville, Maryland) containing 40% (v/v) of heat-inactivated autologus plasma, 100 U/ml of penicillin G and 2.5 μg/ml of streptomycin was prepared.

Each sample of estrone, estradiol-17β, estriol, testosterone, progesterone, and 20α-dihydroprogesterone (Sigma Chemical Co., St. Louis, Missouri) was dissolved in ethanol at serial concentrations between 10^{-1} and 10^4

ng/ml in 10-fold dilutions. An additional series of progesterone concentrations was prepared at 2×10^3, 4×10^3, 6×10^3, and 8×10^3 ng/ml. The effects of ethanol on incorporation of ^{3}H-thymidine into lymphocytes were checked in a preliminary experiment with a concentration range between 10^{-3} and 1% (v/v) of the culture medium. Slight suppression was observed at concentrations exceeding 0.5%, but no appreciable change in incorporation was detected at concentrations below 0.2%. Mean incorporation of ethanol control cultures was 99.8 ± 13.6% (n = 50) in the presence of 0.2% of ethanol.

Two-way MLR were prepared by the addition of 0.05 ml of each of the two sets of lymphocyte suspensions from two different individuals to each well of a flat-bottomed microtest plate (Towa Chemical Co., Tokyo) with a graduated dropper in quadruplicate. Then 0.1 ml of steroid solution was further added to each well with the final concentration of ethanol not exceeding 0.2% (v/v). Culture conditions were similar to those employed for PHA-stimulated cultures,[4] with the modifications that the first 6 day culture was followed by 18 hour culture in the presence of 0.5 μCi per well of ^{3}H-thymidine (specific activity 5.0 Ci/mmole, Radiochemical Centre, Amersham, England). Extraction of DNA and counting of the incorporated ^{3}H-thymidine were done as described previously.[4] Average counts per minute (cpm) of the quadruplicate samples were calculated and the results were expressed in terms of percentage incorporation of the control culture of the identical mixture without the addition of steroids. The results were evaluated statistically by Student's t test.

The effects of the steroids on lymphocyte viability were assessed by trypan blue dye exclusion at the end of culture under identical conditions. None of the six steroids tested showed cytotoxic activity toward lymphocytes at the concentrations tested.

Results

Effects of estrogen on the incorporation of ^{3}H-thymidine by lymphocytes. As shown in Fig. 1 and Table I, neither estrone nor estriol caused any change in incorporation of ^{3}H-thymidine into lymphocytes at the concentrations used. However, the presence of estradiol-17β at 10^4 ng/ml produced a definite reduc-

tion in ^{3}H-thymidine incorporation into lymphocytes with a statistically significant difference from the control culture.

Effects of testosterone and progestins on the incorporation of ^{3}H-thymidine by lymphocytes. The results are shown in Fig. 2. Testosterone caused no appreciable change in incorporation of ^{3}H-thymidine at the concentrations examined. An apparent reduction was observed in the presence of progesterone at 10^4 ng/ml (51.7 ± 9.6%) with a statistically significant difference from the control culture ($p < 0.001$). Although a slight decrease in incorporation was detected with 20α-dihydroprogesterone at 10^4 ng/ml (78.8 ± 18.9%), the difference from the control was not statistically significant. The suppressive effect of progesterone at concentrations differing by 2×10^3 ng/ml between 10^5 and 10^4 ng/ml are shown in Table II. The mean incorporation of ^{3}H-thymidine did not change significantly up to the concentration of 10^3 ng/ml. However, the mean incorporation began to decrease significantly at 2×10^3 ng/ml (79.3 ± 7.8%, $p < 0.025$), and diminished gradually with increasing concentrations of progesterone to reach a minimum incoropration at 10^4 ng/ml.

Comment

A dose-dependent reduction in incorporation of radioactive thymidine into lymphocytes was observed in the range of progesterone concentrations between

2×10^3 and 10^4 ng/ml, and this is in good agreement with the concentrations in which the suppressive effects of the steroid on lymphocyte response to PHA[3, 4] were detected in our previous work. It has been reported that progesterone concentration in the human placenta ranges from 2×10^3 to 6×10^3 ng/gm of tissue throughout pregnancy.[5, 6] Thus, the local concentration of progesterone displays complete agreement with the effective concentration in vitro of the steroid in the allogeneic cultures in this study as well as in the PHA-stimulated cultures.[3, 4] Therefore the present data further support the notion that progesterone probably acts as an immunosuppressant at its site of production rather than at the systemic level. This idea is strengthened by a recent elegant experiment in which rejection of hamster skin subcutaneously grafted to rats is prolonged in the presence of progesterone-contained silicone rubber capsules.[7]

Since inhibition by progesterone is apparently nonspecific, the actual role of progesterone in immunoregulation during pregnancy should be considered in view of the stages during which the suppressive effect is at work. Blocking antibodies against fetal antigens in mice[8] and the presence of specific serum factors that block maternal immune response to placental antigens[9] or to paternal antigens[10] and IgG antibodies eluted from human trophoblastic basement membranes[11] have been implicated in immunologically specific mechanisms which protect the fetus from maternal rejection. These immune controls would be mandatory for the implanted ovum to survive and a certain time period would be required for establishment of these mechanisms. There has been evidence to show the presence or active synthesis of progesterone in dividing rabbit or rodent ova at peri-implantation stages.[12, 13] Taking these data into account, together with the fact that the highest concentration of progesterone in the human placenta occurs in the earliest period after implantation, it is reasonable to assume that immunosuppression by progesterone in a nonspecific manner could be an important factor for the initial development of the embryo in utero until the specific immune mechanisms are established. If the immunologic role of progesterone is presumed for the peri-implantation stage, it is particularly intriguing that antiserum to progesterone delayed nidation and affected deleteriously the development of the embryo when it was injected into pregnant rats at the peri-implantation stage.[14]

Unexpected significant suppression was detected with estradiol-17β in this study, which did not occur in PHA-stimulated cultures. The steroid may contribute to immunoregulation during pregnancy alternatively through the induction of an immunosuppressive protein,[15] because the effective concentration in vitro is considerably higher than that in vivo in the human placenta.[16]

Laminaria use in midtrimester abortions induced by intra-amniotic prostaglandin $F_{2\alpha}$ with urea and intravenous oxytocin

A laminaria tent was used as an adjunct during midtrimester abortion to attempt to shorten the injection-abortion interval without adversely affecting the frequency of infection, hemorrhage, failed abortion, or cervical laceration. Eighty patients, between 14 and 20 weeks' gestation and desiring pregnancy termination, were randomized into three groups. Abortion was initiated by an intra-amniotic infusion of 20 mg of prostaglandin $F_{2\alpha}$ and 80 gm of hyperosmolar urea in Ringer's lactate (135 ml total volume), followed by oxytocin infused intravenously at 333 mU/min. Group I (N = 28) received no additional therapy; Group II (N = 23) had laminaria placed at the time of the abortifacient injection and removed 4 hours later; Group III (N = 29) had laminaria placed 4 hours prior to injection and removed at the time of injection. The injection-abortion intervals in these three groups were 17.76, 20.80, and 12.96 hours, respectively. This study illustrates that a laminaria tent placed 4 hours prior to injection is significantly more effective than a laminaria tent placed at the time of injection, and produces a shorter mean injection-abortion interval than that in patients receiving no laminaria. Furthermore, laminaria augmentation results in no demonstrable increase in the frequency of serious complications. (AM. J. OBSTET. GYNECOL. 134:260, 1979.)

MANY DIFFERENT procedures to terminate midtrimester pregnancies have been proposed. Various abortifacients, including hypertonic saline, hyperosmolar urea, prostaglandins, and prostaglandin analogues, have been used either alone or in combination and have been administered by different routes. Augmentation of these agents with intravenous oxytocin has also been employed in an attempt to shorten the treatment-abortion interval and to lower the dosage of the abortifacient(s). Unfortunately, none of these procedures for performing second-trimester abortion is ideal. As a result, searches for efficacious and safe methods continue.

The use of intracervical laminaria tents with different abortifacients has been recently investigated.[1–8] In this study we sought to determine whether use of a laminaria could shorten the time from prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)-urea infusion to fetal passage without adversely affecting the frequency of infection, hemorrhage, failed abortion, or cervical trauma. A secondary goal was to determine which of two time schedules for laminaria insertion was preferable.

Material and methods

Eighty women, aged 14 to 44 years, with no concurrent medical illnesses, were admitted to Brooke Army Medical Center, Fort Sam Houston, Texas, for elective midtrimester abortions. During this interval the study was carried out by a single group of investigators.

All subjects were prospectively divided by random

Table I. Clinical characteristics

	Group I	*Group II*	*Group III*
No. of patients	28	23	29

†Means of the three groups were not statistically different.

numbers into one of three groups described below. In each patient the vagina and abdomen were carefully washed with povidone-iodine* solution. Transabdominal aminocentesis was performed aseptically with a No. 18 spinal needle after 2 cc of 1% lidocaine infiltration, and 50 cc of amniotic fluid were withdrawn. All patients were given a single intra-amniotic infusion of 20 mg of $PGF_{2\alpha}$† and 80 gm of hyperosmolar urea‡ in Ringer's lactate (135 cc total volume), followed immediately by oxytocin in 5% dextrose and 0.45% saline infused intravenously at 333 mU/min.

Group I (N = 28) received no additional therapy. In Group II (N = 23) a 5 mm in diameter, "thick" laminaria§ was placed immediately after abortifacient injection and removed 4 hours later. The laminaria was coated with sterile lubricating jelly‖ and its string was tied to a povidone-iodine–soaked vaginal pack that protruded past the introitus. In Group III (N = 29) the laminaria and vaginal pack were placed 4 hours prior to injection and removed at the time of injection.

Patients failing to pass all or parts of the placenta within 2 hours after fetal expulsion were defined as having an incomplete abortion and subjected to curettage under general anesthesia. In all subjects, after completion of the abortion, cervices were carefully inspected for potential cervical-vaginal fistulas and lacerations.

Table I characterizes the three groups of patients. Maternal age and weeks of gestation were comparable for all three groups. However, both laminaria-treated groups (II and III) had a larger percentage of multiparas than did Group I, the controls.

Three criteria were used to compare and evaluate abortifacient efficacy: (1) the proportion of subjects aborting within 24 hours of the trial period, (2) the proportion of subjects aborting within 48 hours of the trial period, and (3) the mean abortion time of those subjects aborting within the 48 hour trial period.

Four serious complications were specifically defined and studied: (1) hemorrhage (blood loss equal to or greater than 500 cc or requiring transfusion); (2) infection (two temperatures of at least 100.4° F, taken 6 hours or more apart, and associated with a tender uterus and positive cervical or blood cultures); (3) failed abortion (failure to pass the fetus within the first 48 hours after amnioinfusion); and (4) cervical trauma (a laceration or cervicovaginal fistula confirmed by postabortion inspection).

An analysis of variance was used to compare mean maternal ages and gestational lengths. The hypothesis that the mean injection-abortion intervals were the same in Groups I, II, and III was also tested by a single-factor analysis of variance. The failed abortions were not included in this analysis. After determining that these means were significantly different, pairwise comparisons of the means of the three groups were made by the Scheffé test.[9]

The cumulative abortion rate of each group was studied as a function of time from the intra-amniotic instillation of $PGF_{2\alpha}$-urea. The number of abortions occurring within 16 hour intervals was compared by means of a chi-squared contingency table. The 32 to 48 hour groups, because of small sample sizes, were pooled with the 16 to 32 hour groups for this analysis.

Results

Characterization of abortion. The mean injection-abortion intervals for patients aborting within 48 hours are given in Table II. These means for the total sam-

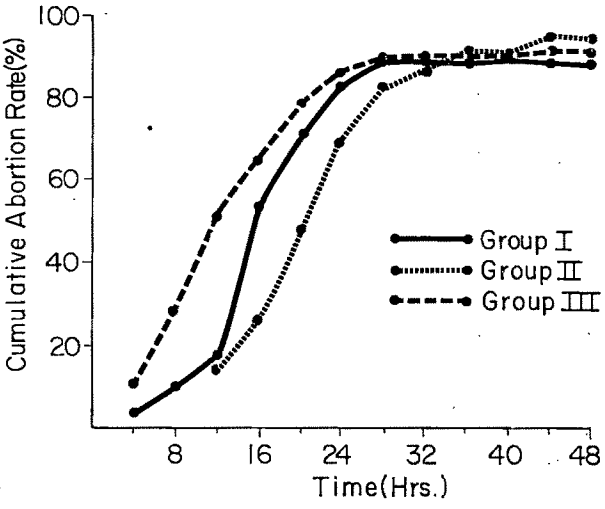

Fig. 1. The cumulative abortion rate graphed as a function of time from the intra-amniotic instillation of $PGF_{2\alpha}$-urea (in nulliparous and parous patients). Three treatment schedules are compared: $PGF_{2\alpha}$-urea alone (Group I), simultaneous laminaria $PGF_{2\alpha}$-urea (Group II), and pretreated laminaria $PGF_{2\alpha}$-urea (Group III).

ples of Groups I, II, and III were significantly different ($F_{2,\ 73} = 5.28$, $p < 0.01$). The injection-abortion interval between the two laminaria groups was significantly shorter (at an over-all significant level of $p < 0.05$) in Group III than Group II. The laminaria-pretreated patients (Group III) aborted 4.80 hours sooner (at an over-all significant level of $0.10 < p < 0.15$) than the control subjects without laminaria (Group I). The difference in mean abortion intervals between Groups I and II of 3.04 hours was not statistically different. Similar patterns existed for the mean abortion times of nulliparas and multiparas among the groups. However, group comparisons for nulliparas were not made because the F test for analysis of variance was not significant at $p < 0.05$, possibly due to reduction in sample size; group comparisons were not made for multiparas because of small sample sizes.

Fig. 1 displays the cumulative percentage of all patients who aborted over a 48 hour trial period. The number of patients in each group aborting in the first 16 hour interval versus the subsequent 32 hour interval was significantly different ($\chi^2_{(2)} = 9.19$; $p < 0.025$). This was due to the large difference between Groups II and III. The pretreatment laminaria patients (Group III) aborted more efficiently during the first 16 hours after $PGF_{2\alpha}$-urea amnioinfusion; at 24 hours after initiation of treatment a larger percentage of Group III (86.2%) had aborted than either Group I (82.1%) or Group II (69.2%). At 48 hours, however, the cumulative abortion rates of the three study groups became similar (Group I, 89.3%; Group II, 95.7%; and Group III, 93.1%).

Placental delivery. In over half (57% of Group I, 52% of Group II and 62% of Group III) of all patients the placenta was delivered within 2 hours of fetal expulsion. For those remaining subjects, the curettage rate for retained placentas of 42.5% (34/80 patients) represented the total of incomplete and failed abortions, and is similar to that usually observed for midtrimester abortion.[4]

Complications. Of all patients, 76% had uncomplicated abortions. However, among the remaining 19 patients with one or more serious complications (Table III), the frequency of these problems was not adversely affected by the addition of either simultaneous or pretreatment laminaria augmentation. The frequency of serious complications among all laminaria-treated patients (23.1%), was quite similar to our control subjects in Group I (25.0%) and compared closely with the complication rate (24.1%) of 116 patients of Duenhoelter, Gant, and Jimenez[8] treated with simultaneous laminaria and intra-amniotic $PGF_{2\alpha}$.

The incidence of serious complications (Table III) was similar among the three study groups. Among the four subjects who failed to abort the fetus within 48 hours after amnioinfusion, in only one of these patients (Group I) did the fetus not eventually pass. In this patient, the pregnancy was carefully terminated with

transvaginal use of ring clamps under general anesthesia. The most common complication was blood loss, which usually occurred during or before operative removal of the placenta. Two of these nine patients required blood transfusions. The incidence of infection in our series was closely related to the length of the infusion to fetal abortion interval. Among nine patients with febrile morbidity only one aborted in less than 16 hours. All of these patients responded well to uterine evacuation and parenteral antibiotics. Two cases of posterior vertical cervical lacerations, one 1 cm and the other 4 cm, occurred in nulliparous laminaria-pretreated patients.

Comment

The combined use of intra-amniotic $PGF_{2\alpha}$-urea is an effective method to terminate pregnancies in the midtrimester, as noted by several groups in England[10, 11] and the United States,[6, 12] and confirmed in our series. King and colleagues[13] recently showed that the minimal effective dose of $PGF_{2\alpha}$, as an augmenting agent with 80 gm of hyperosmolar urea, is not more than 5 mg. This compares with 20 mg of $PGF_{2\alpha}$ used in our study and the earlier series of King and associates.[12]

We sought to determine the effectiveness of a single laminaria tent placed only for the minimal time necessary to allow for adequate laminaria diameter expansion. A 4 hour period of laminaria insertion was believed appropriate because Hale and Pion[14] showed that close to maximal laminaria diameter swelling occurred within 4.6 hours of insertion; even an additional 15.7 hours of insertion time achieved only 1.2 mm further enlargement in diameter.

The greatest difference in the mean injection-abortion interval among the three groups is between the two laminaria groups. However, laminaria insertion at the time of abortifacient injection (Group II) did not significantly shorten the injection-abortion interval. This result supports the findings of other studies.[4, 6] Perhaps laminaria are ineffective when inserted concurrent with abortifacient initiation because (1) cervical dilation from the abortifacients may have been greater than the rate of intrinsic laminaria expansion and (2) a "plug effect" by the laminaria and its vaginal pack may have mechanically impeded fetal abortion.

By contrast, laminaria tents inserted 4 hours prior to abortifacient injection shortened the injection-abortion interval. Recent studies by Stubblefield and associates,[2] using intra-amniotic $PGF_{2\alpha}$, and Bieniarz and associates,[3] using an intramuscularly administered prostaglandin analogue, also showed that laminaria pretreatment makes termination of pregnancy a more rapid event. These investigators used as many as four laminaria, which were left in the cervix overnight for 12 to 18 hours prior to prostaglandin use.[3, 5] Their increased number of laminaria tents may have contributed to shorter abortion intervals than ours. In the series of Stubblefield and associates[5] of 230 pretreatment patients, the mean injection-abortion interval was shorter with two laminaria compared to one laminaria, and improved further when three laminaria were employed. It is less likely that the longer length of pretreatment used by Stubblefield and associates[5] had a beneficial effect because the mean injection-abortion interval for single laminaria use in pretreated patients showed no improvement over our results with only 4 hours' pretreatment.

Our total complication rate of 23.8% cannot be ignored. Perhaps combining intramuscular administration of a prostaglandin analogue with laminaria pretreatment[3] will not only be as rapid as but also safer than our method. In our series retained placenta, hemorrhage, and infection were problems which had similar frequency in both control and laminaria-augmented subjects. As noted independently by both Stubblefield and associates[5] and Lischke and Gordon,[15] and confirmed in our series, cervical rupture, a complication of midtrimester abortion,[16] can still occur despite use of laminaria. Therefore, we examine cervices after all midtrimester abortions, including those utilizing laminaria.

Laminaria tents may potentially cause other serious problems. These include migration toward the uterine fundus if collar devices are not used,[17] incarceration of the laminaria in the cervical canal,[18] and even laminaria fragmentation with loss of the fragments in the uterine cavity.[18] We failed to observe such complications.

In conclusion, a single laminaria tent placed 4 hours prior to $PGF_{2\alpha}$-urea injection produced the shortest injection-abortion interval when compared to (1) laminaria placed at the time of injection and (2) no laminaria treatment. This decrease in the abortion time is not accompanied by a demonstrable increase in the frequency of serious complications.

Discussion

DR. JOSEPH BIENIARZ, Chicago, Illinois. The development of a safe, simple, and efficient method of midtrimester pregnancy termination forms a continuous challenge to fertility control. Dr. Strauss has made an effort to limit the complications and to shorten the induction-abortion time (IAT) by laminaria insertion in patients treated with intra-amniotic instillation of Prostin PGF_2 and urea, combined with intravenous infusion of syntocinon. He used a prospective randomized design to assess the significance of the differences between the mean IAT in the two study groups—(1) one with laminaria inserted at the onset of treatment and (2) the other inserted 4 hours earlier—and (3) a control group treated without laminaria insertion.

With three pairs of means to be compared the authors were forced to use the controversial least significant difference after the analysis of variance, instead of the simple t test. Such repeated comparisons are not independent; therefore, the probability values associated with these statistics do not have the conventionally accepted meaning. The investigator is left with the impression that he has more information than is truly available. It can be shown that with three treatments, the observed value of t for the greatest difference will exceed the tabulated 5% level about 13% of the time; with six treatments the figure is 40%. Thus, when the investigator thinks he is making a t test at the 5% level, he is actually testing at the 13% level for three treatments.*

The three groups were well matched with respect to maternal and gestational age (Table I). They were not matched as to parity (Table III), which is an important omission. While the control Group I, with a long 18 hour IAT, consists almost exclusively of nulliparas, the laminaria-pretreated Group III had a short 9 hour IAT, known to be related to multiparity.

A simple laminaria tent inserted at the onset of induction did not increase the efficiency of treatment. A single laminaria tent inserted 4 hours earlier and withdrawn when treatment was started shortened the IAT significantly, and did not increase the rate of complications. In our experience three to four laminarias inserted snugly into the cervix act better than a single one, if they remain longer—at least 12 hours. Laminaria act slowly and gradually dilate the cervix. Their main advantage consists in protecting the cervix from trauma and disruption caused by forceful rapid dilatation or by intravenous infusion of a potent oxytocic. In this way, cervical incompetency can be avoided.

*Since this original discussion by Dr. Bieniarz, the authors have revised their statistical method and have substituted the more conservative Scheffé test for the least significant difference after the analysis of variance.

CHAIRPERSON

Department of Obstetrics and Gynecology. Applications and nominations are sought for the position of Chairperson, Department of Obstetrics and Gynecology, The University of Texas Health Science Center at San Antonio. Qualifications include evidence of excellence in the areas of teaching, clinical, research and administrative experience. Briggs, Department of Pharmacology, The University of Texas at San Antonio, 7703 Floyd Curl Drive, San Antonio, Texas, 78284. Applications should be accompanied by a Curriculum Vitae and by the names of at least three persons from whom letters of reference can be obtained. An Equal Opportunity/ Affirmative Action Employer.

1979 ORIENT TOURS

For Doctors Attending Tokyo, Oct. 25-31, IXth World Congress of Gynecology and Obstetrics

$544 TOTAL ROUNDTRIP AIRFARES
Los Angeles/San Francisco - Tokyo
Land services NOT necessary to qualify

Oct. 21-31: On scheduled jumbo jet flights of scheduled airlines at lower airfares than on known charter flights. **No land arrangements necessary.** Only 50 doctors with six or more months membership in American Medical Association or American College of Obstetrics and Gynecology, with their wives, will qualify either group of 100 eligible people for these very low airfares.

ALSO AVAILABLE

Tours combining airfares with land arrangements. Very highest quality throughout, such as deluxe and top first-class hotels, and in certain tours extensive sightseeing, dinner parties, and folklore shows to assure that you will enjoy the Orient, not just see it.

TOKYO ONLY—$899—Oct. 21-31—11 days
For doctors concentrating their time on the medical sessions in Tokyo who desire only airfares, hotel, and transfers.

JAPAN ONLY—$1099—Oct. 21-31—11 days
For doctors unable to be absent from their practices very long who want to visit the classical city of Kyoto, in addition to Tokyo.

TOKYO-HONG KONG—$1249—Oct. 23-Nov. 5—14 days
Designed to enable doctors to concentrate their professional time at the medical sessions in Tokyo and enjoy vacation time in Hong Kong.

ORIENT HILITES—$1399—Oct. 23-Nov. 7—16 days
For doctors with limited time who want significant Orient coverage. Includes the "core" of the Orient: Japan, Taiwan, Philippines, Hong Kong.

ORIENT GRAND—$1849—Oct. 23-Nov. 12—21 days
Offers the ultimate, practically all of the Far East: Japan, Taiwan, Philippines, Bali) Indonesia, Singapore, Thailand, Hong Kong. If you have time, this is the program for you.

Sonicaid, the first family of Doppler ultrasound instruments for obstetrics, offers you ease of use, accuracy, clarity of data presentation; rugged design, dependable solid-state circuitry and Sonicaid attention to users' service needs.

(top left) The newest family member is the modular FM3R Fetal Monitoring System. It offers a numerical index of the effectiveness of contractions, a choice of monitoring modes and a fast-response recorder for accurate charting of baseline variability.

(bottom left) Save nursing time with an MD800 Remote Memory Display. As many as four sets of FHR/contractions traces from up to six monitors can be reviewed.

(chair, top unit) The D205 Fetal Heart Detector is our best known family member. Over 25,000 have been sold worldwide. Rechargeable battery-powered for portability, it presents fetal heart sounds via loudspeaker or headset. Like other Sonicaid transducers, the D205's is repairable assuring years of economical service. (The similar D205M Fetal Heart Detector, not pictured, is AC powered for extended audio monitoring.)

(chair, bottom unit) The economical FM2 Fetal Monitor is finding increasing use both in the labor room and in non-stress testing.

(right, table) The ultimate portable diagnostic instrument: the D100 Pocket Fetal Heart Detector. You can listen not only on its headset, but also—and more conveniently—on its built-in loudspeaker.

Meet the family face to face. Our nationwide team of representatives will be happy to introduce you. For information or a demonstration write or phone us. P.O. Box 714 KC, Fredericksburg, Virginia 22401 TOLL FREE 800/336-7212, Va. calls 703/898-6820

SONICAID

Over a decade of leadership in Doppler ultrasound

CHAIRPERSON DIVISION OF OB/GYN

Albert Einstein Medical Center, Philadelphia, Pennsylvania, a major affiliate of Temple University seeks a full time Chairperson of OB/GYN with appropriate academic rank at the Medical School.

This is a key position which requires the ability to provide leadership to staff physicians and an academic and professional commitment to patient care education and research.

The Northern Division is a 600 bed acute general hospital which has on its North Philadelphia campus a major research facility, an extended care facility and a major rehabilitation hospital.

Please submit your curriculum vitae and suggested references to the **Chairman, Search Committee, ALBERT EINSTEIN MEDICAL CENTER, Northern Division, Old York and Tabor Roads, Philadelphia, Pa. 19141.** Inquiries will be held in strictest confidence.

Equal Opportunity Employer

ASSOCIATE DIRECTOR, RESIDENCY PROGRAM IN OBSTETRICS AND GYNECOLOGY.

Work with the Program Director of the integrated residency sponsored by the Northeastern Ohio Universities College of Medicine Affiliated Hospitals at Canton, Ohio, and coordinated through the Canton Medical Education Foundation, Inc. with Aultman Hospital and Timken Mercy Medical Center as the participating institutions. Academic rank; full-time hospital based; salary and fringe benefits negotiable; professional liability insurance provided; background in residency teaching, research, and administration desirable. Prefer ABOG diplomate. Excellent growth potential in area of 400,000+. Send CV to Alvin Langer, M.D., Program Director, Residency in Obstetrics and Gynecology, c/o Canton Medical Education Foundation, Inc., 2600 Sixth Street, S.W., Canton, Ohio 44710; (216) 452-9911, ext. 554. EOE.

going into practice ? consider north carolina

North Carolina's Office of Rural Health Services Offers You:

—the chance to discuss private practice opportunities in 100 communities from the coast to the mountains

—the chance to investigate National Health Service Corps practice opportunities

—the opportunity to work with physician extenders if you so desire

—the chance to join a group, partnership, association or to establish a new practice

—the opportunity for you and your spouse to visit a community with the right kind of life-style and medical practice organization

—the opportunity to participate in the North Carolina Area Health Education Centers Program

The Office of Rural Health Services Has Information On 100 Communities For Your Consideration

announces

NEW DURICEF®
(CEFADROXIL MONOHYDRATE)

A new oral cephalosporin for urinary tract infections due to *Escherichia coli, Proteus mirabilis,* and *Klebsiella* sp. distinguished by sustained, higher urine levels

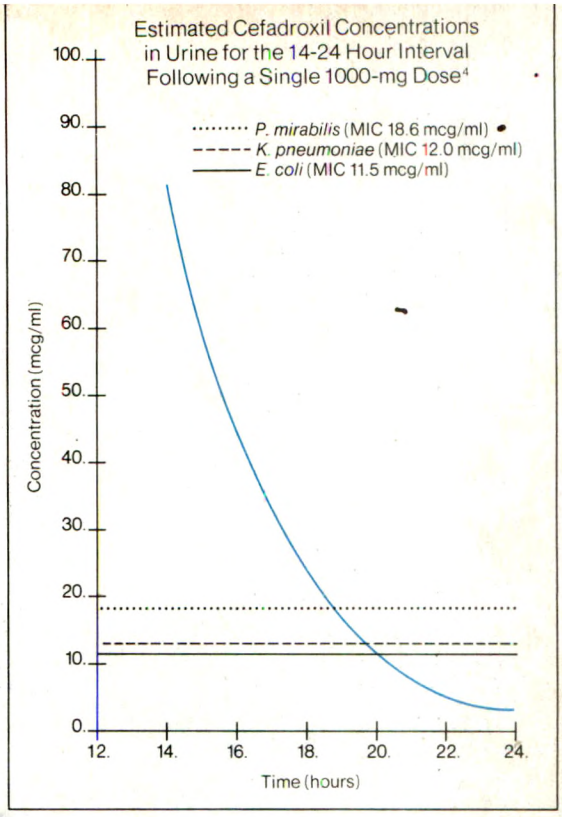
Numerous human pharmacological studies have now clearly established that the outstanding metabolic characteristic of cefadroxil, which differentiates it from other presently marketed cephalosporins such as cephalexin and cephradine, is its prolonged duration of action."[1]

"...for cephalosporins, a longer half-life might be more useful than higher peak levels."[2]

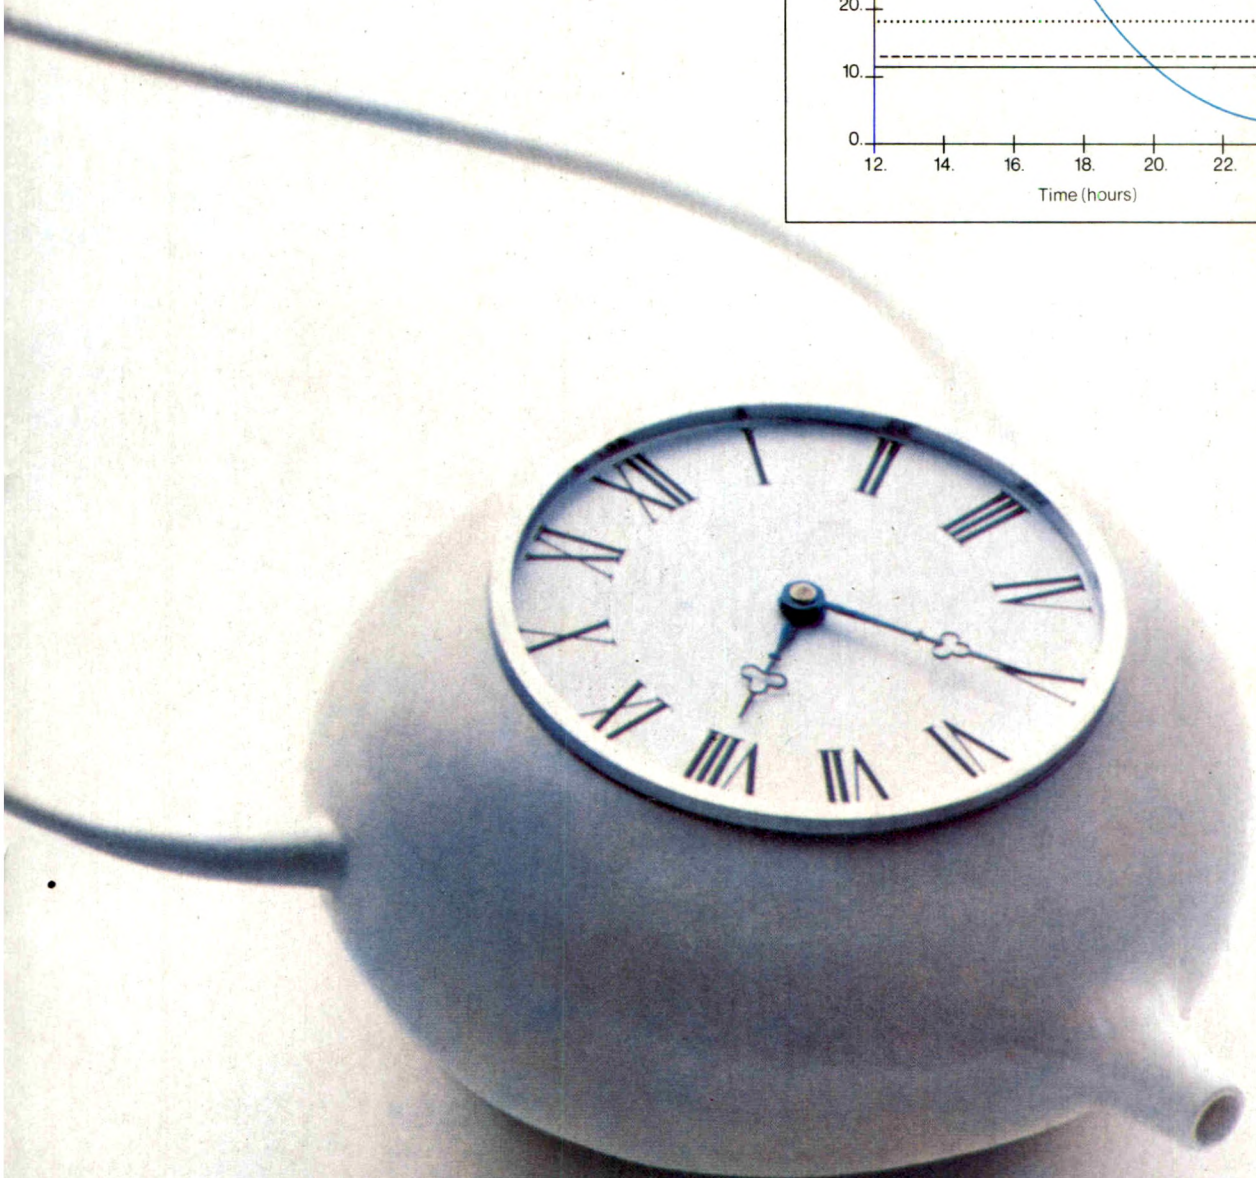
For complete prescribing information, see last page of this advertisement.

For treatment of urinary tract infections due to *Escherichia coli*, *Proteus mirabilis*, and *Klebsiella* sp.

NEW DURICEF®
(CEFADROXIL MONOHYDRATE)



A new b.i.d. oral cephalosporin offering tangible clinical benefits...



PROLONGED DURATION OF ACTION

"Numerous studies have shown that effective antimicrobial activity in urine is most important in curing urinary tract infections.... a continuous urinary antibiotic concentration above the MIC of the infecting organism can cure the majority of urinary tract infections, whether of renal or bladder origin."[3]

SUSTAINED HIGHER URINE LEVELS

- Cefadroxil concentration in urine is maintained well above the MICs for all typical urinary pathogens for 12 hours and, in most instances, for 18 hours.[3]
- After single equivalent doses, the antibiotic concentration in urine is three times higher for cefadroxil at 6 to 12 hours than for cephalexin[3]
- The prolonged duration of action is due to a more gradual urinary excretion rate compared to cephalexin and cephradine.[1,3]
- Twenty-four hours after ingestion, approximately 93% of cefadroxil is recovered in the urine.[3]

Mead Johnson
PHARMACEUTICAL DIVISION

NEW

CAPSULES, 500 mg.

DURICEF®

(CEFADROXIL MONOHYDRATE)

For urinary tract infections due to *Escherichia coli*, *Proteus mirabilis*, and *Klebsiella* sp.

PROVEN CLINICAL EFFICACY

- 93% (263 of 282 patients) cure rate of acute urinary tract infections due to indicated organisms in the patients treated with cefadroxil (two 500-mg. capsules b.i.d.) in numerous multicenter studies.[5]

IIGH DEGREE)F SAFETY

Laboratory parameters in more than 175 studies in 15 countries have failed to reveal any drug-related changes regarded as clinically significant.[4]

In none of these studies was there any tendency for cefadroxil to accumulate in the serum nor has nephrotoxicity been reported.[4]

DURICEF can be used in patients with renal insufficiency at reduced dosages (see full prescribing information).

There is evidence of partial cross-allergenicity between the penicillins and the cephalosporins.

The most frequent adverse reaction has been nausea...rarely severe enough to warrant cessation of therapy. Administration with food decreases the chances of nausea occurring and does not affect absorption.

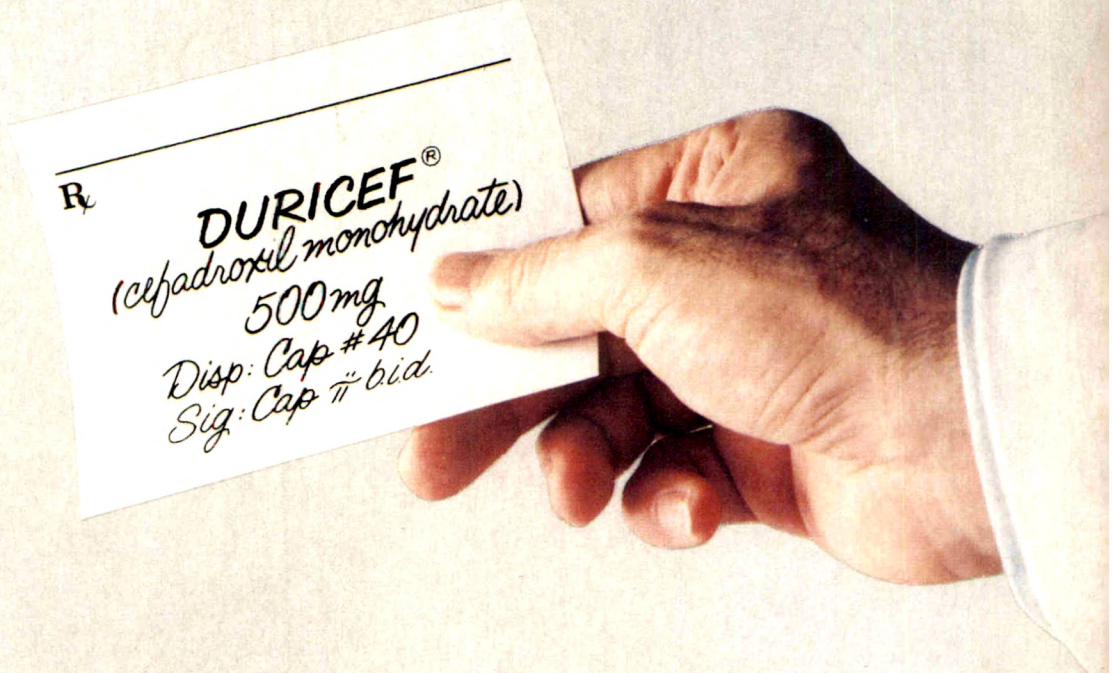
B.I.D. CONVENIENCE AND COMPATIBILITY WITH FOOD

B.I.D. CONVENIENCE



Sustained high urine levels in comparison with other oral cephalosporins justify a simple two-capsule b.i.d. regimen in urinary tract infections.

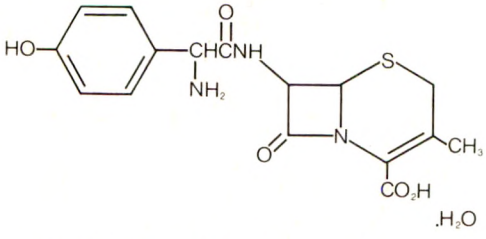
COMPATIBILITY WITH FOOD

Concomitant administration of DURICEF with food does not affect its rate or extent of absorption. This may be helpful in diminishing potential gastrointestinal complaints occasionally associated with oral cephalosporin therapy.

ENHANCED DOSAGE COMPLIANCE

The convenient regimen of DURICEF—two capsules b.i.d., at breakfast and dinner—improves the chances for patient compliance and increases the likelihood of patients completing therapy as prescribed.

Mead Johnson
PHARMACEUTICAL DIVISION



For complete prescribing information, see following page.

DURICEF®
(CEFADROXIL MONOHYDRATE)

A new oral cephalosporin offering tangible clinical benefits... plus b.i.d. convenience

DESCRIPTION: DURICEF® (cefadroxil monohydrate) is a semisynthetic cephalosporin antibiotic intended for oral administration. It is a white to yellowish-white crystalline powder. It is soluble in water and it is acid-stable. It is chemically designated as 7-[[D-2-amino-2-(4-hydroxyphenyl)acetyl]amino]-3-methyl-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid monohydrate. It has the following structural formula:

Clinical Pharmacology—DURICEF (cefadroxil monohydrate) is rapidly absorbed after oral administration. Following single doses of 500 and 1000 mg., average peak serum concentrations were approximately 16 and 28 mcg./ml., respectively. Measurable levels were present 12 hours after administration. Over 90 percent of the drug is excreted unchanged in the urine within eight hours. Peak urine concentrations are approximately 1800 mcg./ml. during the period following a single 500 mg. oral dose. Increases in dosage generally produce a proportionate increase in DURICEF urinary concentration. The urine antibiotic concentration was maintained well above the MIC of all typical urinary pathogens for 12 hours and, in most instances, for 18 hours.

MICROBIOLOGY: *In vitro* tests demonstrate that the cephalosporins are bactericidal because of their inhibition of cell-wall synthesis. DURICEF is active against the following organisms *in vitro*:

Escherichia coli — *Klebsiella species*
Proteus mirabilis

Note—Most strains of *Enterococci (Streptococcus faecalis* and *S. faecium)* are resistant to DURICEF. It is not active against most strains of *Enterobacter species, P. morganii,* and *P. vulgaris.* It has no activity against *Pseudomonas* or *Herella species.*

Disc Susceptibility Tests—Quantitative methods that require measurement of zone diameters give the most precise estimates of antibiotic susceptibility. One recommended procedure (CFR Section 460.1) uses cephalosporin class disc for testing susceptibility; interpretations correlate zone diameters of this disc test with MIC values for DURICEF. With this procedure, a report from the laboratory of "resistant" indicates that the infecting organism is not likely to respond to therapy. A report of "intermediate susceptibility" suggests that the organism would be susceptible if the infection is confined to the urinary tract, as DURICEF produces high antibiotic levels in the urine.

INDICATIONS: DURICEF (cefadroxil monohydrate) is indicated for the treatment of urinary tract infections caused by *E. coli, P. mirabilis,* and *Klebsiella species.*

Note—Culture and susceptibility tests should be initiated prior to and during therapy. Renal function studies should be performed when indicated.

CONTRAINDICATION: DURICEF (cefadroxil monohydrate) is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNING: IN PENICILLIN-ALLERGIC PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE USED WITH GREAT CAUTION. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PENICILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES OF PATIENTS WHO HAVE HAD REACTIONS TO BOTH DRUGS (INCLUDING FATAL ANAPHYLAXIS AFTER PARENTERAL USE).

Any patient who has demonstrated a history of some form of allergy, particularly to drugs, should receive antibiotics cautiously and then only when absolutely necessary. No exception should be made with regard to DURICEF (cefadroxil monohydrate).

PRECAUTIONS: Patients should be followed carefully so that any side-effects or unusual manifestations of drug idiosyncrasy may be detected. If a hypersensitivity reaction occurs, the drug should be discontinued and the patient treated with the usual agents (e.g., epinephrine or other pressor amines, antihistamines or corticosteroids).

DURICEF (cefadroxil monohydrate) should be used with caution in the presence of markedly impaired renal function (creatinine clearance rate of less than 50 ml/min/1.73 M^2). (See Dosage and Administration.) In patients with known or suspected renal impairment, careful clinical observation and appropriate laboratory studies should be made prior to and during therapy.

Prolonged use of DURICEF may result in the overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Positive direct Coombs tests have been reported during treatment with the cephalosporin antibiotics. In hematologic studies or in transfusion cross-matching procedures when antiglobulin tests are performed on the minor side or in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it should be recognized that a positive Coombs test may be due to the drug.

USAGE IN PREGNANCY: Although no teratogenic or anti-fertility effects were seen in reproductive studies in mice and rats receiving dosages greater than the normal human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

ADVERSE REACTIONS: Gastrointestinal—The most frequent side-effect has been nausea. It was infrequently severe enough to warrant cessation of therapy. Administration with food decreases nausea and does not decrease absorption. Diarrhea and dysuria have also occurred.

Hypersensitivity—Allergies (in the form of rash, urticaria, and angioedema) have been observed. These reactions usually subsided upon discontinuation of the drug.

Other reactions have included genital pruritus, genital moniliasis, vaginitis, and moderate transient neutropenia.

DOSAGE AND ADMINISTRATION: DURICEF (cefadroxil monohydrate) is acid stable and may be administered orally without regard to meals. Administration with food may be helpful in diminishing potential gastrointestinal complaints occasionally associated with oral cephalosporin therapy.

Adults—The usual adult dose is one g. (two 500 mg. capsules) two times per day for patients with normal renal function. In patients with renal impairment, the dosage of cefadroxil should be adjusted according to creatinine clearance rates to prevent drug accumulation. The following schedule is suggested. In adults, the initial dose is 1000 mg. of DURICEF (cefadroxil monohydrate) and the maintenance dose (based on the creatinine clearance rate [ml/min/1.73M^2]) is 500 mg. at the time intervals listed below.

Creatinine Clearances	Dosage Interval
0-10 ml/min	36 hours
10-25 ml/min	24 hours
25-50 ml/min	12 hours

Patients with creatinine clearance rates over 50 ml/min may be treated as if they were patients having normal renal function.

Children—Dosage and safety have not yet been established in children.

HOW SUPPLIED: DURICEF® (cefadroxil monohydrate) capsules 500 mg. for oral administration in an opaque maroon cap and opaque white body No. 0 hard gelatin capsule. On each half capsule printed in black is "MJ" and "500." Available in bottles of 24 capsules (NDC 0087-0784-41) and 100 capsules (NDC 0087-0784-42).

FETUS, PLACENTA, AND NEWBORN

13,14-Dihydro-15-keto-prostaglandin $F_{2\alpha}$ concentrations in human plasma and amniotic fluid

R. B. GHODGAONKAR, B.PHARM.
N. H. DUBIN, PH.D.
D. A. BLAKE, PH.D.
T. M. KING, M.D., PH.D.
Baltimore, Maryland

An antiserum to 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}M$) was prepared and a radioimmunoassay evaluated in various reproductive states. $PGF_{2\alpha}M$ plasma concentration was 63.6 ± 10.3 pg/ml (mean ± SEM) in cycling women. The concentration fluctuated throughout the menstrual cycle and pregnancy, but no discernible patterns were noted. $PGF_{2\alpha}M$ concentrations were elevated at the time of urea + oxytocin induced abortion (238 ± 54 pg/ml) and during late stages of normal labor (352 ± 107 pg/ml) but were not elevated during labor prior to 7 cm dilatation. Following intra-amniotic instillation of 5 mg of $PGF_{2\alpha}$ tromethamine into the amniotic sac, $PGF_{2\alpha}M$ concentration increased in the amniotic fluid. In the plasma of these patients there was an eighteenfold rise in plasma $PGF_{2\alpha}M$ concentration compared to a 3.5-fold rise in $PGF_{2\alpha}$ at 1 hour, suggesting changes in $PGF_{2\alpha}M$ may be more easily detected than the parent compound. While $PGF_{2\alpha}M$ may be a useful index of $PGF_{2\alpha}$ production, it appears that $PGF_{2\alpha}M$ is of little value in predicting the occurrence of uterine contraction. (AM. J. OBSTET. GYNECOL. 134:265, 1979.)

CIRCULATING physiologically active prostaglandins have a short half life due to rapid metabolism by the lungs, liver, and other organs.[1] There is also evidence that prostaglandins are metabolized to inactive forms within the cells of origin prior to secretion.[2, 3] It has been suggested, therefore, that measuring the metabolite rather than the parent compound might better reflect changes in production of prostaglandins.[4] The major circulating metabolite of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) is 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}M$). This paper describes $PGF_{2\alpha}M$ plasma concentrations in various reproductive states and compares amniotic fluid (AF) and plasma $PGF_{2\alpha}$ with $PGF_{2\alpha}M$ during midtrimester abortions induced with intra-amniotic hyperosmolar urea and $PGF_{2\alpha}$.

From the Department of Gynecology and Obstetrics, The Johns Hopkins Hospital.

These studies were carried out under Contract AID/csd-3627.

Received for publication March 20, 1978.

Revised June 29, 1978.

Accepted July 19, 1978.

Reprint requests: Dr. T. M. King, Department of Gynecology and Obstetrics, The Johns Hopkins University, School of Medicine, Baltimore, Maryland 21205.

Material and methods

Antiserum preparation. Antiserum was prepared by coupling $PGF_{2\alpha}M$ to bovine serum albumin (BSA) by the carbodiimide method and rabbits were immunized as previously described.[5] An average of 29 molecules of $PGF_{2\alpha}M$ were coupled to each molecule of BSA as determined by retention of $PGF_{2\alpha}M$ trace following dialysis. Blood, obtained by cardiac puncture, contained a peak titer at 1 month, and the titer remained

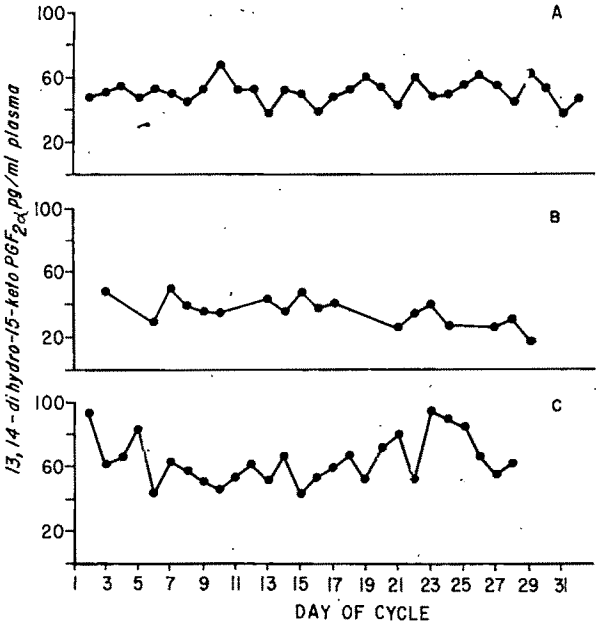

Fig. 1. Plasma $PGF_{2\alpha}M$ concentrations in three normal women observed serially throughout the menstrual cycle. Day 1 s the first day of menstrual bleeding.

high for 10 months at which time the rabbit was killed and blood collected.

Radiommunoassay. A standard curve was prepared in tricine-buffered saline (TBS) containing gelatin (1 mg/ml) for the range of 0 to 320.0 pg of $PGF_{2\alpha}M$. Antiserum was diluted with TBS (1:20,000) and 0.1 ml of this dilution was added to a tube containing 0.1 ml unextracted plasma, 0.1 ml standard, or 0.1 ml TBS (zero tube) and was incubated for 30 minutes at room temperature. The radioisotope [5,6,8,11,12,14(n)-^{3}H]13,14-dihydro-15-keto-$PGF_{2\alpha}$ (specific activity 85 Ci/mmole) was obtained from Amersham Searle Corporation, Chicago, Illinois. A stock solution containing 10 μCi/ml in ethanol: water (7:3) was stored at −20° C. On the day of assay, 25 μl was removed, dried under nitrogen, and redissolved in 10.6 ml of TBS. 0.1 ml volume (approximately 2,500 cpm with a mass of 10 pg) was added to each tube and incubated overnight at 4° C.

The next day the antibody-bound complex was precipitated by addition of 1.0 ml of 68% saturated ammonium sulfate suspension containing 4% calcium sulfate as described previously.[6] The contents were mixed and allowed to stand at 4° C for 10 minutes. The tubes were centrifuged for 30 minutes at 2,000 rpm at 4° C. Then 0.8 ml of supernatant (free phase) was added to 10 ml of toluene-based scintillation cocktail and counted for 10 minutes. The corresponding values were read from the standard curve and expressed in terms of $PGF_{2\alpha}M$ concentration in picograms per milliliter of sample.

The minimum mass of $PGF_{2\alpha}M$ necessary to cause a displacement of ^{3}H-$PGF_{2\alpha}M$ from the antibody, which was significantly different from the zero tube, was 1.25 pg and the working range extended to 100 pg. "Charcoal-stripped" plasma gave blank values that averaged 2.1 pg/0.1 ml. The correlation coefficient between added and observed mass of $PGF_{2\alpha}M$ was 0.99 and the slope of the regression line was 0.89 with the Y intercept close to zero. The within-assay coefficient of variation was 5% and the between-assay coefficient of variation was 16%. The cross-reaction of related prostaglandins was tested for their ability to displace ^{3}H-$PGF_{2\alpha}M$ from the antibody relative to $PGF_{2\alpha}M$. The results found are as follows: 13,14-dihydro-$PGF_{2\alpha}$, 3%; 15-keto-$PGF_{2\alpha}$, 0.01%; 13,14-dihydro-15-keto-PGE_2, 1%; 15-keto-PGE_2, <0.01%.

$PGF_{2\alpha}$ was measured by the method of Salmon and Amy.[7] The antiserum was provided by Dr. S. M. M. Karim, Singapore. The antibody shows some cross-reaction with other prostaglandins of the F series, but cross-reaction with the E series is less than 1%. Interassay coefficient of variation was 15% and intra-assay coefficient of variation was 9%.

Clinical studies. One blood sample was obtained from each patient and plasma $PGF_{2\alpha}M$ was determined and compared in the following groups of women: (1) those in the follicular stage of the menstrual cycle; (2) those using a combined oral contraceptive (5 mg norgestrel and 50 μg ethinyl estradiol); (3) those with uncomplicated pregnancies, 17 to 20 weeks after the last menstrual cycle (this group was further separated into those at less than and those at greater than 7 cm dilatation; (4) elective abortion parients, 17 to 20 weeks pregnant, at the time of abortion (these patients were injected with intra-amniotic hyperosmolar urea (80 gm) followed by intravenous oxytocin (332 mU/min.).

The following patients had multiple blood samples drawn. Daily plasma samples from three women throughout the menstrual cycle and sequential samples from two pregnant women were also assayed. Eight multiparous patients over 18 years of age seeking termination of a midtrimester pregnancy, and who gave informed consent, participated in the following study. An 18 gauge butterfly needle was placed in the right antecubital vein for collection of blood samples prior to and at timed intervals (t = 0, 0.25, 1, 4, 8, and 12 hours) following abortifacient injection. Polyethylene tubing was inserted into the amniotic cavity through which AF was withdrawn and replaced by 134 ml of 5% dextrose containing 80 gm urea and 5 mg $PGF_{2\alpha}$

tromethamine. This initiation of the injection was considered time zero (t = 0). This procedure is discussed in detail in another publication.[8] The tubing was left in place so that AF could be sampled at intervals corresponding to the blood sampling prior to rupture of membranes. Urea added to prostaglandin standards was found not to affect the radioimmunoassay displacement curves.

All blood samples were collected and stored on ice in heparinized tubes containing indomethacin (5 ug/ml blood) and the plasma was immediately separated by centrifugation and frozen until assayed. All samples were assayed in duplicate.

Results

Plasma $PGF_{2\alpha}M$ concentrations for women in various reproductive states are listed in Table I. Levels of $PGF_{2\alpha}M$ at the time of induced abortion were significantly higher than pregnant women not in labor at the same stage of pregnancy (65.5 ± 8.6 SEM vs. 238.3 ± 54.5 pg/ml). There was no detectable increase in $PGF_{2\alpha}M$ in early labor (< 7 cm), however, there was a significant increase at 8 cm to 1 hour post partum (Table I). Although $PGF_{2\alpha}M$ values fluctuated throughout the cycle, there appeared to be no discernible pattern (Fig. 1). Values fluctuated in individual patients throughout pregnancy, but again there appeared to be no pattern (Fig. 2).

Following $PGF_{2\alpha}$ instillation into the amniotic sac, the AF concentration of $PGF_{2\alpha}$ increased from 0.15 ± 0.01 to 6,250 ± 1,300 ng/ml in 15 minutes. After 1 hour, there was a decline in $PGF_{2\alpha}$ concentration which reached 1,370 ± 970 ng/ml by 12 hours. The disappearance half life (time for concentration to fall to 50% of the back-extrapolated time zero concentration) was 4.5 hours (Fig. 3). The apparent volume of distribution of PGF was calculated by dividing the injected dose of $PGF_{2\alpha}$ (5 mg) by the extrapolated concentration of $PGF_{2\alpha}$ at time zero (7,000 ± 1,500 ng/ml) and found to be 710 ± 150 ml. $PGF_{2\alpha}M$ increased in AF within 15 minutes of injection from 0.24 ± 0.05 to 53.7 ± 24.8 ng/ml. These levels continued to rise until 8 hours when the concentration reached 377 ± 103 ng/ml.

In the plasma, $PGF_{2\alpha}$ concentration increased by 1 hour after intra-amniotic administration of $PGF_{2\alpha}$ from 0.32 ± 0.03 to 1.09 ± 0.27 ng/ml. There was no significant change in these levels over the next 12 hours. $PGF_{2\alpha}M$ increased from 0.07 ± 0.01 to 0.76 ± 0.31 ng/ml plasma in 15 minutes and remained above the preinjection values for 12 hours. The average concentration in $PGF_{2\alpha}M$ in plasma increased eightfold at 1 hour after amniotic injection of

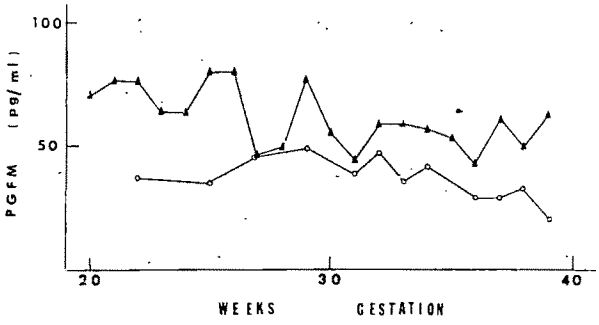

Fig. 2. Plasma $PGF_{2\alpha}M$ concentrations in two women followed serially during pregnancy.

$PGF_{2\alpha}$ compared to a 3.5-fold rise in average $PGF_{2\alpha}$ concentration (Fig. 4).

Comment

Changes in the pattern of plasma $PGF_{2\alpha}$ have not been shown during the menstrual cycle[9] despite the fact that increased levels have been shown in endometrial tissue[10] and jet washes of endometrium[11] during the luteal phase. In the present study, while there was a day-to-day variation in plasma $PGF_{2\alpha}M$, no obvious pattern in plasma $PGF_{2\alpha}M$ was apparent during the menstrual cycle of any of the three subjects studied. No difference was seen between women using combined oral contraceptives and control women in the follicular stage of their cycle (61 ± 7.4 vs. 63.6 ± 10.3 pg/ml).

Following intra-amniotic administration of 5 mg $PGF_{2\alpha}$, the AF disappearance rate of $PGF_{2\alpha}$ was found to be 4.5 hours. The volume of distribution was 710 ± 150 ml. This volume agrees well with that found for urea in the same patients.[8] These results suggest that the $PGF_{2\alpha}$ was distributed to an apparent space larger than AF, the volume of which was estimated to be about 200 to 300 ml based on the amount removed at the time of injection. The other compartments to which the $PGF_{2\alpha}$ is most likely distributed includes the

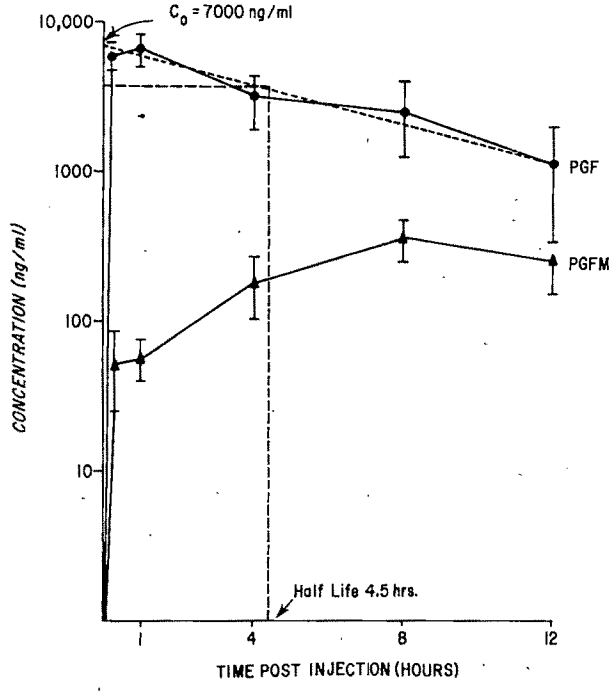

Fig. 3. Concentration of $PGF_{2\alpha}$ and $PGF_{2\alpha}M$ in AF following intra-amniotic $PGF_{2\alpha}$ (5 mg) administration. $PGF_{2\alpha}$ was administered along with 80 gm urea to induce abortion. Dotted line through $PGF_{2\alpha}$ curve represents the regression line (fitted to an exponential decay curve) for $PGF_{2\alpha}$ extrapolated to time 0 to estimate the concentration at time 0 (C_0). Number of patients = 8. Vertical line indicates standard error of the mean.

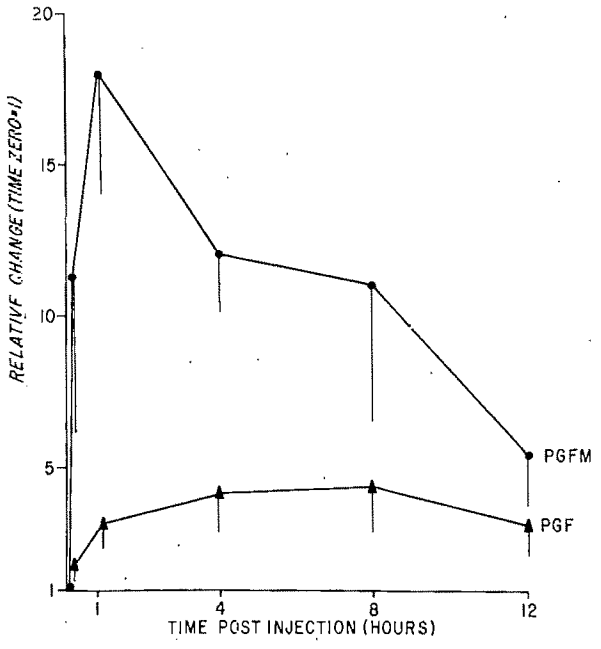

Fig. 4. Relative change in plasma $PGF_{2\alpha}$ and $PGF_{2\alpha}M$ following intra-amniotic administration of 5 mg $PGF_{2\alpha}$. Time 0 relative change was defined as 1. $PGF_{2\alpha}$ was administered along with 80 gm urea to induce abortion. Number of patients = 8. Vertical line indicates standard error of the mean.

fetus and placenta as demonstrated pharmacokinetically for urea in rhesus monkeys.[12]

Following intra-amniotic injection of $PGF_{2\alpha}$ AF $PGF_{2\alpha}M$ concentration increased gradually with time, indicating some metabolism occurring in the fetal compartment and/or maternal conversion and transfer back to the fetus. The relative change in $PGF_{2\alpha}M$ at 1 hour after injection was greater (peak = 18 × initial value) compared to $PGF_{2\alpha}$ (3.5 × initial value), suggesting changes in $PGF_{2\alpha}M$ may be more easily detected than $PGF_{2\alpha}$. The patterns of $PGF_{2\alpha}$ and $PGF_{2\alpha}M$ concentration with time are similar to those in three patients reported previously by Cornett, Harrison, and Kirton[3] despite the fact that a 40 mg dose of $PGF_{2\alpha}$ without urea was injected intra-amniotically compared to our 5 mg dose. That study also differed in that the initial $PGF_{2\alpha}M$ levels were about tenfold greater than in this report which may be related to the specificity and sensitivity of the antibody. Plasma levels of $PGF_{2\alpha}M$ reported in the literature range from 38[4] to 1,400 pg/ml[3] as measured by radioimmunoassays. Our values are in the lower range and agree in magnitude with values obtained by the tedious but more precise method of gas chromatography–mass spectrophotometry.[13]

$PGF_{2\alpha}$ is a potent oxytocic agent which is endogenously produced in increasing amounts by actively contracting uteri.[14, 15] Since circulating $PGF_{2\alpha}$ is rapidly metabolized by prostaglandin dehydrogenase and Δ^{13} reductase,[1] it has been suggested that $PGF_{2\alpha}M$ may more accurately reflect changes in production of $PGF_{2\alpha}$.[4] Also, in vitro $PGF_{2\alpha}$ production has been documented after blood is collected[16] whereas this seems not to be the case for $PGF_{2\alpha}M$ yielding an additional advantage of $PGF_{2\alpha}M$ measurements.

In this study, a 3.6-fold increase in plasma $PGF_{2\alpha}M$ levels was found in induced abortion patients at the time of high uterine activity as compared to controls of the same gestational age not in labor. In early labor, there was no detectable rise in plasma $PGF_{2\alpha}M$ until after 7 cm dilatation, at which time levels were significantly increased. While $PGF_{2\alpha}M$ may be a good index of $PGF_{2\alpha}$ production, it appears that $PGF_{2\alpha}M$ is of little value in predicting the occurrence of uterine contractions.

We wish to thank Dr. John Pike, The Upjohn Co., Kalamazoo, Michigan, for the gift of prostaglandins, and Dr. J. H. Robinson of Merck Sharp & Dohme, Rahway, New Jersey, for indomethacin.

Reduced uterine blood flow and fetal hypoxemia with acute maternal stress: Experimental observation in the pregnant baboon

HISAYO O. MORISHIMA, M.D., PH.D.
MING-NENG YEH, M.D.
L. STANLEY JAMES, M.D.
New York, New York

The effects of maternal hyperexcitability on the fetus were studied in 17 baboons. In the period of agitation, induced by stressful stimulus such as exposure to bright light or by clamping of the toe, the mother exhibited an increase in arterial blood pressure and, in some instances, arrhythmia. These changes were accompanied by an increased uterine activity and reduced uterine blood flow, and resulted in a decrease in heart rate and arterial oxygenation in all fetuses. Fetal recovery was prompt after maternal agitation was terminated, either by removal of the stimulus or by sedation with pentobarbital or nitrous oxide. This sedation also prevented a decrease in uterine blood flow when stress was repeated. (AM. J. OBSTET. GYNECOL. 134:270, 1979.)

THE EFFECTS of obstetric anesthesia on the fetus have been extensively investigated during the past decade. In contrast, scant attention has been paid to the possible adverse fetal effects of maternal apprehension and pain, which frequently occur when medication is withheld during labor and delivery. Previous reports have shown that maternal excitability may lead to acute fetal distress in the rhesus monkey.[1–3] It was postulated that the observed fetal asphyxia was due to an increased sympathetic activity in the mother resulting in enhanced uterine contraction and impaired uteroplacental perfusion. Indeed, it has been demonstrated that intravenous infusion of catecholamines into the mother can reduce uteroplacental blood flow in the sheep[4–6] and lead to severe fetal asphyxia in the rhesus monkey.[7]

The present study on pregnant baboons was carried out as part of our continuing series of investigations on the influence of maternal pain and agitation upon the fetus.

Material and methods

A total of 25 experiments were performed on 17 pregnant baboons (*Papio* hybrid) with their fetuses at gestational ages ranging from 146 to 171 days (term 185 days). Initially, the animals were operated on under nitrous oxide and halothane anesthesia.[1] Catheters were placed in the maternal femoral artery and vein. In the fetus, either a carotid artery and jugular vein or a femoral artery and vein were catheterized at hysterotomy. Maternal and fetal ECG electrodes were applied, and thermistor probes were placed in the fetal esophagus and maternal colon. A catheter was also placed in the amniotic cavity in order to monitor intra-amniotic pressure. In eight experiments a pulsed Doppler flow transducer was implanted around the ascending branch of the uterine artery. Maternal core temperature was kept at approximately 38° C by means of a heating pad and an overhead source of infrared radiation. Maternal and fetal arterial pressure and heart rate as well as flow rate in a uterine artery and intra-amniotic pressure were continuously recorded. The heart rate was measured using either a cardiotachometer from the arterial pulse pressure or the R wave of the ECG. Uterine blood flow was measured

‡P < 0.01 compared with well-oxygenated fetus.

using an ultrasonic pulsed Doppler system, and blood velocity change was expressed in percent from the control value.[8] Uterine activity was expressed in Montevideo units (MVU).[9] Blood samples were obtained simultaneously from the maternal and fetal artery at frequent intervals and analyzed for pH, Pco_2, and Po_2 using Radiometer microelectrodes and a Radiometer gas analyzer. The base deficit was calculated using the Siggaard-Andersen nomogram. The oxygen saturation (Sao_2) was estimated using the nomograms for adult and fetal baboons.[10]

Postoperatively, the animal was placed in the semilateral position and lightly restrained. She was sedated with nitrous oxide (75% to 80% in oxygen), and ventilated mechanically in order to maintain maternal arterial pH values between 7.38 and 7.48. The animals were allowed to recover for at least two hours after the hysterotomy (control period), after which they were subjected to stressful stimulation. The fetuses were divided into two groups according to their acid-base state prior to the study. On 16 occasions the fetuses were well oxygenated, a mean pHa being 7.32 ± 0.014 (SE) and Sao_2, 56% ±3.1%. In the remaining nine experiments the fetuses were acidotic and hypoxemic, with a mean pHa of 7.26 ± 0.018, and Sao_2 of 29% ± 2.5% (asphyxiated group).

During the experiment the gas mixture of nitrous oxide and oxygen was replaced by room air, but positive-pressure ventilation was maintained. After the mother was completely awake, a bright light was shone on her face (nine experiments) or a rubber-covered clamp was applied to a toe (16 studies) for 5 to 20 minutes (average 15 minutes). Similar stimuli were applied again following readministration of nitrous oxide and oxygen. On five occasions the mothers were given an intravenous injection of pentobarbitol, 2 to 3 mg/kg prior to or during stimulations. All results were analyzed using the paired t test and considered statistically significant when P values were less then 0.05.

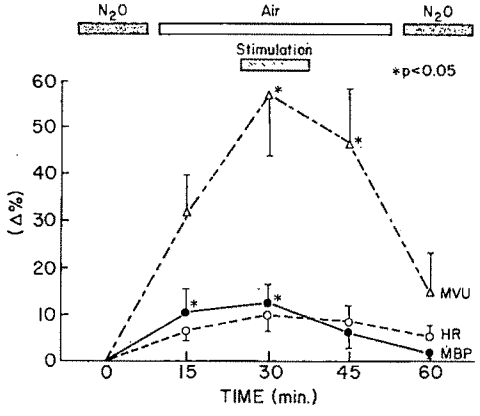

Fig. 1. Proportional changes in uterine activity, expressed in Montevideo units (MVU), maternal heart rate (HR), and mean arterial blood pressure (MBP) during air breathing and stressful stimulation. Increased MVU and MBP during stress were statistically significant compared to prestress values.

Results

Mother. The control values of maternal pH and blood gases, blood pressure, and heart rate prior to each stress experiment are summarized in Table I. After 3 to 5 minutes of air breathing, maternal arterial pressure began to rise significantly ($P < 0.05$) and remained elevated throughout the stimulation. The blood pressure, which was 113 ± 2.5 mm Hg during the control period, rose to 123 ± 3.4 mm Hg during air breathing and to 127 ± 4.5 mm Hg during stressful stimulation. The rise in blood pressure was accompanied by a slight increase in heart rate from 132 ± 4.2 to 141 ± 5.9 beats/minute during air breathing and to 143 ± 5.2 beats/minute during stimulation (Fig. 1). In eight instances sinus arrhythmia was observed during agitation. During air breathing the blood flow, mea-

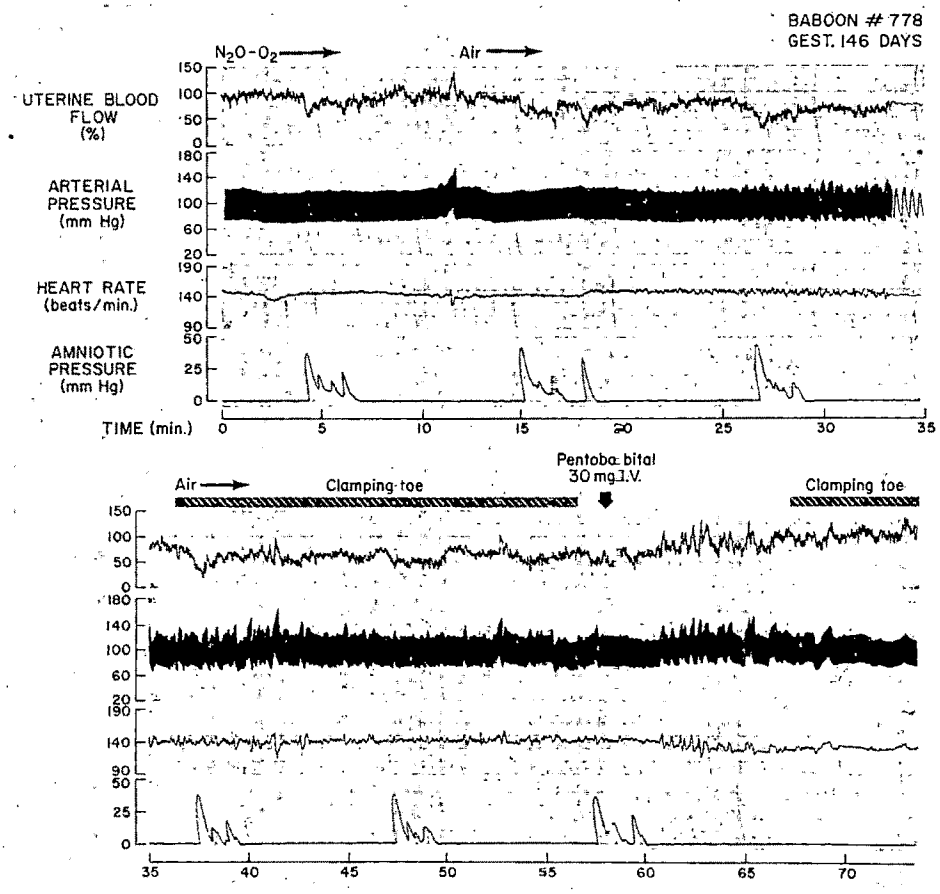

Fig. 2. Typical recording of uterine artery blood velocity (uterine blood flow), maternal arterial pressure and heart rate, and intra-amniotic pressure during air breathing, toe clamping, and following administration of pentobarbital. Note the reduction of blood flow during air breathing. The reduction became more profound during the toe clamping while the animal was breathing air. These changes were accompanied by irregular heartbeat. The toe was clamped again after administration of pentobarbital, but blood flow did not decrease with this stress.

sured in eight experiments, decreased by 7% to 33%. As much as a 70% reduction from the prestress level was observed during stimulation (Table II). Following readministration of nitrous oxide or injection of pentobarbital, the blood flow returned to control levels, and it did not decrease when the stimulus was applied again. A typical recording of changes in the blood flow during stress, before and after intravenous administration of 2 mg/kg pentobarbital, is depicted in Fig. 2. All animals showed mild to moderate spontaneous uterine activity with a mean of 90 ± 8.2 MVU at the end of the control period. Replacement of nitrous oxide with air caused an increase in amplitude and frequency of uterine contractions; the mean MVU rose to 119 ± 11.4 (31% ± 7.9% of control) (Fig. 1). Further increase ($P < 0.01$) to 145 ± 16.3 MVU (59% ± 13.0%) occurred during the stimulation. Elevated uterine activity persisted ($P < 0.05$) even after the stimulus was removed; 130 ± 21.3 MVU (44% ± 12.3%). Following readministration of nitrous oxide for 5 to 10 minutes, the uterine activity declined to a mean MVU value of 104 ± 15.4 (16% ± 8.3%). The maternal acid-base state remained essentially unchanged throughout the experiment. During the period of stimulation at which time uterine activity, blood pressure, and heart rate altered most significantly, values were pHa, 7.44 ± 0.011; $Paco_2$, 29 ± 1.5 mm Hg; base deficit, 3.0 ± 0.68 mEq/L; Pao_2, 97 ± 8.1 mm Hg, and Sao_2, 100%.

Fetus. The indicators of fetal condition prior to stress are shown in Table I. The most notable fetal changes during maternal agitation were in heart rate and arterial oxygenation, particularly in the asphyxiated group (Fig. 3). In the well-oxygenated fetus, heart rate remained essentially unchanged in the 15 minutes following discontinuation of nitrous oxide, but it fell from the prestress value of 184 ± 3.5 to 170 ± 6.9 beats/minute during stressful stimulation. However, in the asphyxiated fetus, it had already fallen from 186 ± 10.0 to 173 ± 6.7 beats/minute during air breathing, and further decreased to 150 ± 4.8 beats/minute ($P < 0.05$) during stress. Fetal Sao_2 fell from 56% ± 3.1% to 44% ± 4.4% during air breathing and 42% ± 4.6% ($P < 0.05$) with stimulation in the well-oxygenated group. In the asphyxiated group, Sao_2 fell from 29% ±2.5% to 22% ± 2.9% following air, and to 20% ± 2.6% ($P < 0.05$) with stress. In both groups of fetuses the heart rate and Sao_2 began to return to the prestress levels after removal of the stimulus while the mothers continued to breathe air. Fetal arterial pressure and acid-base state remained relatively stable throughout the experiment. The lowest mean pHa found during maternal stress was 7.23 ± 0.052 in the well-oxygenated group and 7.20 ± 0.032 in the asphyxiated group.

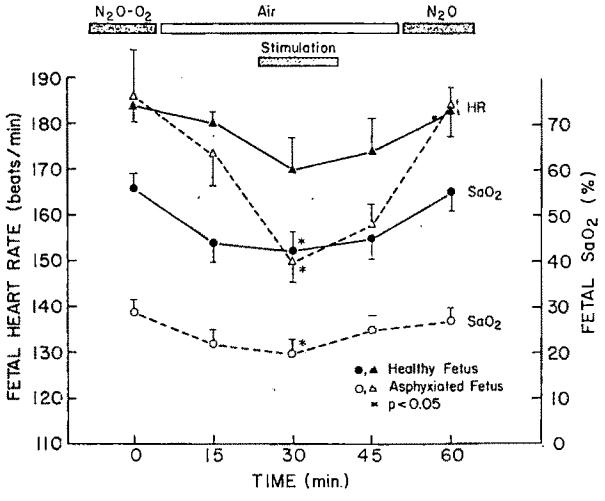

Fig. 3. Changes in fetal heart rate and arterial oxygenation during air breathing and maternal stress. Solid symbols and solid lines represent the well-oxygenated group; open symbols and broken lines, the asphyxiated group. Significant fall in heart rate and Sao_2 are seen during maternal stress in the asphyxiated fetuses.

A typical experiment of shining a bright light into the mother's eyes is seen in Fig. 4. Maternal blood pressure increased and heartbeat became irregular during air breathing. These symptoms were even more pronounced when the light was placed close to her face. Fetal response was minimal during air breathing, but heart rate, arterial pH, and oxygenation decreased following the light. Those variables recovered following readministration of nitrous oxide.

Clamping the mother's toe during air breathing resulted in maternal and fetal responses similar to those produced by the light (Fig. 5). Maternal agitation caused a marked fall in the fetal heart rate (from 190 to 138 beats/minute), pHa, and Sao_2. These values returned gradually toward prestress levels after removal of the clamp.

Comment

These experiments have demonstrated that removal of sedation and exposure to stressful stimuli, such as bright light and pain in the pregnant baboon, can lead to an increase in uterine activity and a reduction in flow rate in a uterine artery. As a result, a decrease in fetal heart rate and oxygenation may occur, particularly in an already asphyxiated fetus. When maternal agitation was eliminated by administering nitrous oxide or pentobarbital, uterine perfusion and the fetal condition improved. The study was performed in a semi-acute

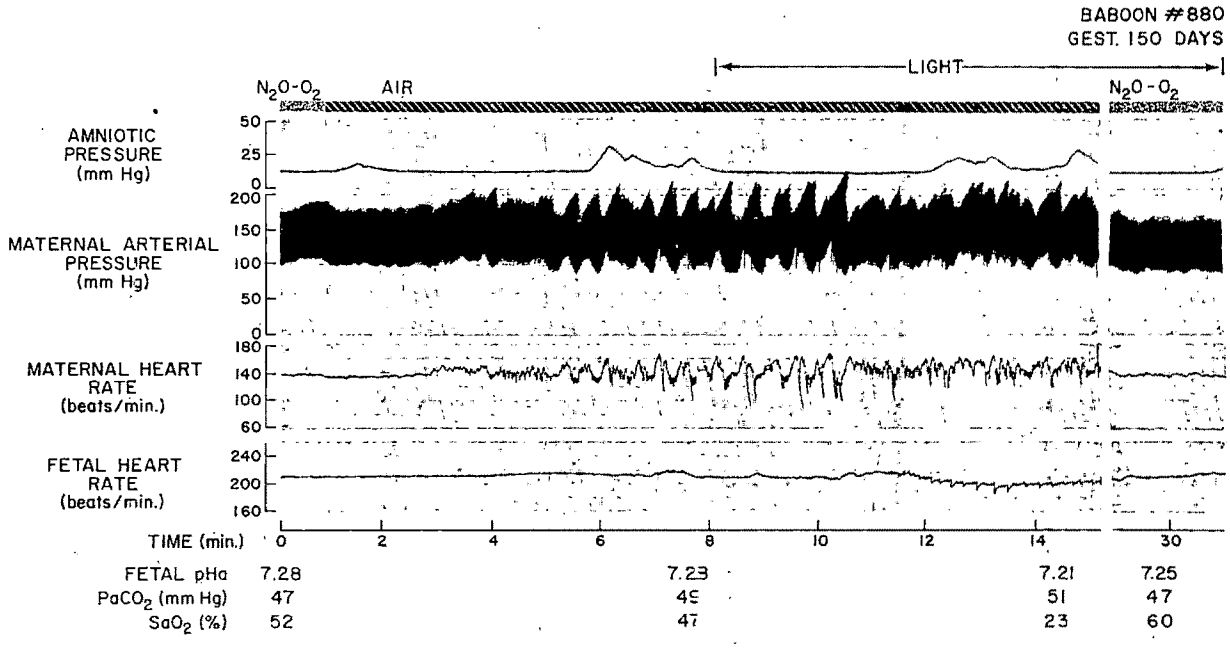

Fig. 4. Typical recording of intra-amniotic pressure, maternal arterial pressure and heart rate, and fetal heart rate during air breathing and exposure to a bright light. Note the decreasing fetal heart rate after shining a light on the mother's face. This was associated with a marked fall in fetal pHa and Sao_2.

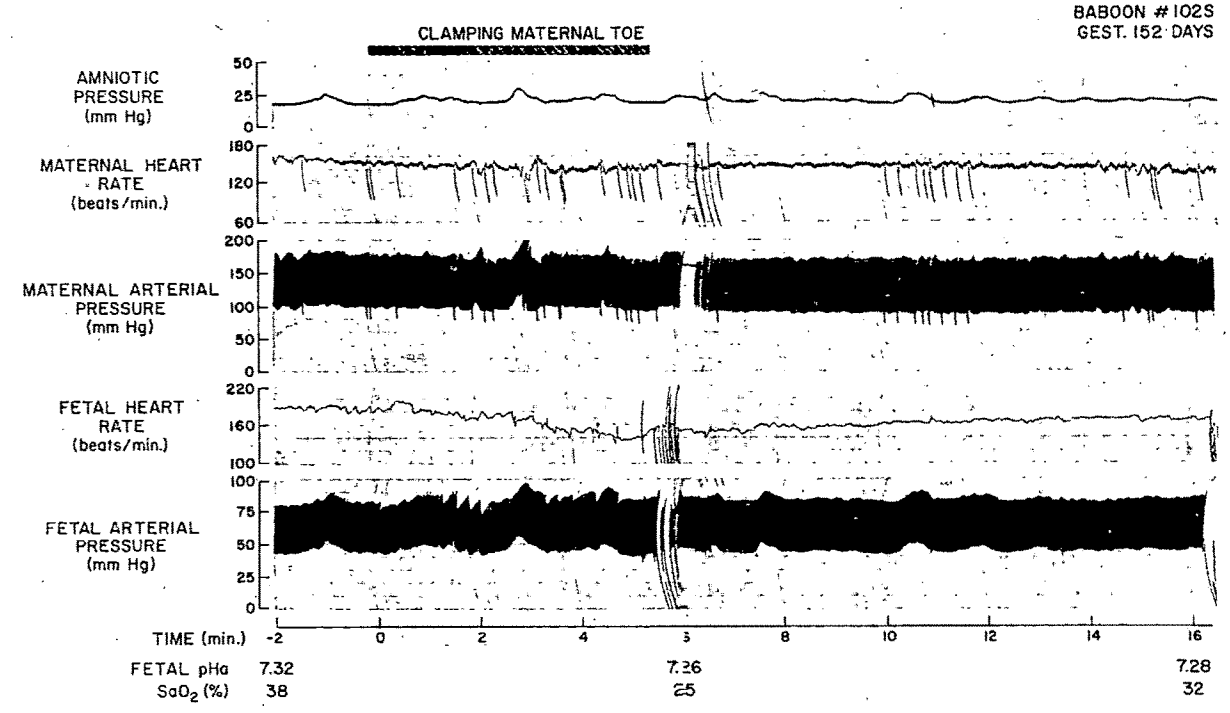

Fig. 5. A segment of the record in which intra-amniotic pressure, heart rate, and blood pressure of the mother and fetus are recorded. Stress was produced by clamping of the mother's toe. As the mother became agitated, there was a fall in fetal heart rate and a decrease in fetal arterial oxygenation, as seen in the bottom record. Note that fetal arterial pressure increases during uterine contractions as increased intra-amniotic pressure is transmitted to the fetus.

preparation, and nitrous oxide had been administered during the control period. Therefore, it might be argued that the condition of the animal during the control period was quite different from the unsedated human subject during labor and delivery. The quality and degree of pain which the baboon is capable of appreciating remain difficult to assess and may be quite unlike the capacity of humans. Nevertheless, reduction of uteroplacental perfusion during the stress undoubtedly plays the main role in fetal hypoxemia as a consequence of decreased oxygen availability. Recently, we have observed similar results in unanesthetized, chronically instrumented pregnant sheep. A marked decrease in uterine blood flow and an increase in arterial pressure occurred during maternal agitation resulting from clamping the earlobe. These changes were prevented by administering diazepam prior to clamping. It has been shown that intravenous infusion of catecholamines into pregnant sheep has resulted in a reduction in uteroplacental blood flow.[4-6] Epinephrine and norepinephrine produced endogenously in response to stress might be expected to show similar effects. In fact, we have some recent data, as yet unpublished, that there is a significant increase in plasma epinephrine and norepinephrine levels during stress in the pregnant baboon. Another study[11] on pregnant women has shown that plasma epinephrine levels increase during labor and delivery; epinephrine values rapidly decreased after delivery. Increased epinephrine levels were significantly reduced after establishing regional anesthesia.

In summary, it can be concluded that maternal agitation may be harmful to the fetus. Under these circumstances, sedation or pain relief in the mother appear to be beneficial not only to the mother but also to the integrity of uteroplacental circulation and, ultimately, to fetal well-being.

Effect of maternal glucose load on fetal activity

SILVIO ALADJEM, M.D.
ANTONIO FERIA, M.D.*
JONATHAN REST
KATHLEEN GULL, B.S.
MARGARET O'CONNOR, B.A.
Chicago, Illinois

The effect of a MGL upon fetal activity has been studied in 39 normal and 54 high-risk pregnant patients between 30 and 42 weeks' gestation. The perinatal morbidity and mortality rates were significantly lower in the group showing an increase in fetal activity following a MGL. It is suggested that this may be useful for identifying the fetus at risk. (AM. J. OBSTET. GYNECOL. 134:276, 1979.)

GLUCOSE is an important source of fetal energy, fetal glucose levels being dependent on maternal supply. Therefore, fetal energy expenditure is, in part, controlled by availability of maternal glucose. A study was undertaken to ascertain the effect of a standard maternal glucose load (MGL) upon fetal activity in normal and high-risk pregnancies.

Material and methods

From the Obstetrical Service of the University of Illinois Hospital in Chicago, 39 normal and 54 high-risk pregnant patients between 30 and 42 weeks' gestation were selected for this study (Table I). All tests were performed between 08:00 and 11:00 A.M. after an overnight fast. Maternal fasting blood sugar (FBS) levels were determined in all cases.

Following a 1 hr baseline recording of fetal heart rate (FHR) and fetal movements (FM), all patients were given either a 100 gm oral glucose load or a 0.5 gm/kg intravenous glucose load. Since the intravenous rather than the oral route is preferred for a glucose tolerance test at our institution, an intravenous load was administered whenever a glucose tolerance test was clinically indicated. Five patients in the normal pregnancy group and 22 in the high-risk group had an intravenous glucose load (29.1%). The remaining 66 patients (70.9%) had an oral glucose load. Maternal blood glucose levels were determined at 1 and 2 hours after oral glucose load and at 15 min intervals for 1 hour after the intravenous load. In all cases FHR and FM were recorded for 2 hours after glucose load. In addition, the morning after the MGL loading test, every fifth patient in both the normal group (8 patients) and the high-risk group (10 patients) underwent a prolonged 3 hours nonstressed monitoring (NSM) without MGL.

The interval time between the MGL and delivery varied between 4 and 22 days. Hewlett Packard equipment was used to monitor FHR and FM. Fetal movements were recorded by way of an external tocodynamometer placed on the maternal abdomen and also identified by the mother verbally and/or by activating an event-marker connected to the uterine channel, thus producing an upward deflection of the stylus.

FHR was obtained through an indirect fetal electrocardiograph (HP 15174A) from the maternal abdomen in 22 normal patients and 40 high-risk patients (66.7%), and by way of an ultrasound amplifier (HP 15180) in the remaining 17 normal patients and 14 high-risk patients (33.3%). The fetal heart beat-to-beat variability as well as reactivity to FM were noted. The percentage of FHR accelerations to FM was also determined.

Two types of fetal movements were identified: (1) isolated movements (I), 12 sec or more apart from each other and (2) multiple movements (M), a series of

isolated movements less than 12 sec apart from each other with an average of four movements per group. For each hour the ratio between multiple and isolated movements (M:I ratio) was calculated.[1] Estriols, hPL, OCT, and labor monitoring tracings were compared with the results of the MGL.

Results

Based on the presence or absence of M:I ratio change, two groups of patients were identified. In the first group (normal MGL test—91.4%), regardless of whether the glucose load was administered orally (Fig. 1) or intravenously (Fig. 2), there was a marked increase in the number of multiple movements which increased the M:I ratio by more than 100 per cent over the fasting level by the end of the second hour after MGL. In the second group (abnormal MGL test—8.6%), the fetal activity remained unchanged and the M:I ratio did not increase under similar experimental conditions (Figs. 3 and 4). The perinatal mortality and morbidity rates were significantly higher ($p < 0.001$) in the second group (Table II). Both normal and high-risk pregnancies were included in the first group; the second group comprised only high-risk pregnancies. The peak of the maternal blood glucose preceded the increase in the M:I ratio in the first group. In the second group the fasting M:I ratio was not affected by the maternal rise in blood glucose level. The percentage of FHR response to FM did not change from the fasting to the fed state in the first group. In the second group, it was initially lower in comparison with the first group, increased briefly following the MGL, and returned to the fasting level thereafter.

In both groups the nonstressed monitoring tracings were interpreted as being of the reactive pattern[9] with the exception of a sinusoidal pattern in a severly affected erythroblastotic infant who died in utero soon thereafter. Prolonged 3 hr NSM sessions during fasting state showed that the M:I ratio did not vary with time (Fig. 5). The estriols, hPL, OCT, and labor monitoring

tracings in the nine cases with either an abnormal perinatal outcome, abnormal MGL, or both are shown in Table III. There was only one abnormal MGL with a normal perinatal outcome in a patient with Class B diabetes. Of the eight cases with an abnormal perinatal outcome, seven has an abnormal MGL test. In only one case the OCT was positive <7 days prior to delivery. Estriols, hPL, and labor monitoring tracings were all within normal limits. The MGL result did not appear to correlate with any pregnancy risk in particular (Table IV).

Comment

The difference in the perinatal morbidity and mortality rates in the two groups identified by the MGL test would suggest the fetuses in the first group to be in homeostatic balance and those in the second group to be at risk. Maternal glucose is the main source of fetal glucose,[5, 11] this being fundamental for the maintenance of brain and heart functions[2] and a major source of fetal energy.[12] Maternal starvation, on the other hand, alters the glucose supply to the fetus by reducing the maternal-glucose concentration difference[12] and fetal glucose uptake.[2, 6] Furthermore, hypoxemic fetuses show no increase in glucose uptake with either increasing maternal glucose levels or increasing glucose gradients.[3] One could therefore speculate that in the presence of an increase in glucose inflow as a result of maternal glucose load in fasting mothers, the fetuses in the first group replenished their reserves and subsequently enhanced their activities, whereas the fetuses in the second group probably either use the glucose for

functions more important than physical activities or may not be able to benefit from the availability of glucose altogether.

The increase of fetal activity following MGL observed in this study is in agreement with the report of Spellacy and colleagues.[13] This increase in fetal activity is characterized by an increase in multiple movements with the consequent increase in the M:I ratio. The nature of these multiple movements, however, is not clear. One suggestion is that multiple movements may represent fetal respiratory movements, total body movements, or a combination of both.[1, 4, 8, 14] However, the effect of a glucose load on fetal respiratory movements, assuming these to be a major component of multiple movements, is unsettled since some studies suggest a resumption of fetal breathing movements when hypoglycemia is corrected by glucose infusion[4, 8] and others have not been able to observe this phenomena.[7] It should be noted, however, that the stressful experimental conditions of insulin-induced hypoglycemia[7] are not entirely comparable to the fasting state and glucose administration of this or other studies.[8, 13] The lack of increase of fetal activity observed in the second group is in agreement with the report of a decrease in fetal breathing movements[4] and a decrease of total movements[10] in compromised fetuses.

Following glucose loading, the peak of the fetal activity increase as represented by the M:I ratio was delayed considerably with respect to the peak of the maternal glucose levels. It is therefore postulated that the triggering factor responsible for the increase in fetal activity is the glucose load through some physiologic process rather than an immediate result of a "glucose shock" or some other unphysiologic mechanism. In abnormal MGL tests, this mechanism is probably impaired. Prolonged NSM without MGL showed the M:I ratio not to increase spontaneously with the passage of time.

All but one of the tracings in these studies were of the reactive pattern variation[9] and were of no predictive value except for the nonreactive sinusoidal pattern in the one case of intrauterine fetal death in a severly erythroblastotic fetus. However, the variation in the test-to-delivery time in this study may be responsible for this lack of correlation. The significance of the transient improvements in the percentage of FHR accelerations to FM following MGL in the abnormal group on the one hand, and the significance of the low percentage of FHR accelerations to FM in the fasting state when compared to the normal group, remain to be established. These findings however, suggest that more sensitive definitions of nonstressed reactivity patterns are needed.

The data of estriols, hPL, and OCT were not notable for their predictive value of perinatal morbidity and death in the abnormal MGL group, except for a positive OCT. However, the MGL was abnormal in seven out of the eight cases with an abnormal perinatal outcome. Larger series may clarify if fetal activity enhancement following maternal MGL may be disturbed earlier than the hormonal or stress assessments, in which case it could become an important tool for early recognition and detection of fetal compromise, particularly since the lack of response does not seem to be characteristic of a given risk factor only. Fetal hyperglycemia may increase plasma lactate and decrease blood pH, thus iatrogenically causing acute fetal distress.[11] As it may have been determined by the presence of fetal bradycardia, this did not occur in this series.

The dehydroepiandrosterone loading test

III. A possible placental function test

MARCOS J. PUPKIN, M.D., F.A.C.O.G.
DAVID A. NAGEY, M.D., PH.D.

Durham, North Carolina

The dehydroepiandrosterone loading test (DLT) has been used in a small population of normal and high-risk obstetric patients, to date, in an attempt to develop a dynamic test of placental function. In spite of its limited applications, it has shown reliability in discriminating, with statistical significance, between high-risk pregnancies that result in normally grown, undistressed infants, and high-risk pregnancies that result in infants showing signs of placental insufficiency. The present report expands the study population by presenting our data on 40 loading tests performed in 37 high-risk and normal obstetric patients. Results of 19 of these DLT's have been previously reported and are included herein for statistical analysis. The DLT utilizes an excess substrate load of dehydroepiandrosterone to assess the maximum capability of the placenta to convert it to estrogen. Although our previous report did not show false positive or negative results in the conversion rates, the present results (40 DLT's) found two (2 out of 17) false positives (12%) and two (2 out of 19) false negatives (11%). The highly significant correlation between DLT result and pregnancy outcome seen previously[2] was preserved. In addition, the data of another five DLT's in four patients are presented. This group includes a pregnancy with a fetus with multiple congenital malformations, two patients with intrauterine fetal death, and a nonpregnant woman. The results are not included in the statistical analysis, but discussion of these results has interesting pathophysiologic implications.
(AM. J. OBSTET. GYNECOL. 134:281, 1979.)

PREVIOUS work from this group[1, 2] has demonstrated that the dehydroepiandrosterone loading test (DLT) may be a valid indicator of placental function. In the limited population studied, the DLT has been shown to be capable of discriminating between high-risk pregnancies resulting in normally grown, undistressed infants, and those resulting in infants with signs of chronic placental insufficiency ($p = 0.001$).

In addition, the DLT has been shown to be capable of discriminating between normal obstetric patients and high-risk obstetric patients who delivered infants with signs of chronic fetal distress.[2]

Chronic placental insufficiency was considered to be present when: (1) the birth weight of the newborn infant was below the tenth percentile for gestational age; or (2) the birth weight was below the twenty-fifth percentile, but with a positive oxytocin challenge test (OCT), or with signs of acute fetal distress during labor; or (3) complete clinical cessation of fetal growth for a period of four weeks or more during the prenatal course as judged by fundal height or ultrasonographic determination of biparietal diameter.

This work was based upon the animal model studies by Pupkin and associates[5] in our group, which in turn was stimulated by Lauritzen's[5] clinical studies utilizing DHEA-S and urinary estrogen determination.[1, 2, 5]

Our reason for continued interest in this work is that a simple, dynamic placental function test, which the DLT appears to be, with a specific predictive value, would provide a useful new tool to clinicians dealing with high-risk obstetric patients, questionable gestational age histories, or equivocal clinical fetal growth parameters.

Material and methods

All of the patients included in this study were identified by and cared for by the Division of Perinatal Medicine, Duke University Medical Center.

As stated previously, this study comprises a total of 40 DLT's in 37 patients, and includes 19 DLT's in 19 patients previously presented.[2]

Table I describes the patient groups studied.

Group A consists of five tests in five normal patients who had uneventful pregnancies and normally grown, undistressed infants.

Group B is composed of 13 tests in 13 high-risk patients who were diagnosed as having chronic placental insufficiency, defined as a birth weight below the tenth percentile, or a birth weight below the twenty-fifth percentile with a positive OCT or manifestations of acute

fetal distress during labor, or a complete clinical cessation of fetal growth for a period of four weeks or more.

Group C contains four tests in four high-risk patients who developed fetal distress during labor, but delivered normally grown infants.

Group D consists of 13 tests in 13 high-risk patients who delivered normally grown, undistressed infants. While some of these patients were chosen because of size-date discrepancies, none exhibited discernible cessation of either uterine size or biparietal growth as estimated by ultrasonography.

Group E contains five DLT's in four patients. The patients in this miscellaneous group will be discussed individually and in detail. It includes one normal nonpregnant patient, two patients with intrauterine fetal death (IUFD), and one patient whose fetus had multiple congenital malformations. Table II presents each patient's high-risk factors, gestational age at the time of the DLT, birth weight, gestational age at the time of birth, and the study group to which the patient was assigned.

In all groups, gestational age was determined clinically by maternal menstrual history and its correlation with uterine size in early pregnancy. In addition, serial ultrasonography and maturity studies were used when needed. In newborn infants, gestational age was corroborated by the Dubowitz score and the percentile category determined by the chart of Lubchenco and colleagues.[3]

The protocol of the DLT is described in full elsewhere,[2] but in brief, comprises the intravenous injection of 25 mg DHEA (5-androsten-3β-ol-17-one*) prepared as a sterile solution of 5 mg DHEA/ml in ethanol-saline (1:1, v:v) by the Duke Hospital Pharmacy. Approximately ten minutes prior to the administration of DHEA, a control blood sample for hormonal analysis is obtained. The DHEA solution is injected as a bolus into the antecubital vein; injection time is fast, not lasting more than five seconds. The vein is then immediately flushed with 10 ml of normal saline. After infusion of the DHEA, 6 ml blood samples for hormone analysis are drawn at 5, 10, 7.5, 15, 30, 45, 60, and 180 minutes. All blood samples are drawn from the same intravenous line.

The DLT involves only a mild discomfort to the patient. This is produced by the ethanol contained in the vehicle, which causes momentary irritation and a burning sensation in the vein of injection. This is a variable phenomenon, however, never lasting for more than 30 seconds in our experience.

Prior to the initiation of the test, each patient signs an informed consent. The informed consent and study protocol have been approved by the Human Experimentation Committee at Duke University Medical Center.

Total serum estrogens are measured by radioimmunoassay using a slight modification (less serum) of the technique described by Aksel and associates[8, 10] which was developed and validated in our laboratory. The cross-reactivities of the antibody are: 80% with estrone,

Group A	—	†	N.S.	N.S.
Group B	—	—	*	‡
Group C	—	—	—	N.S.
Group D	—	—	—	—

N.S. = Not significant.
*$p < 0.05$.
†$p < 0.01$.
‡$p < 0.001$.

100% with 17β-estradiol, 5% with estriol, and 0.0002% with DHEA.

The data are analyzed by fitting the mathematical representation of a physiologic model using a computer program. In brief, the model permits identification of the rate constant of DHEA to estrogen conversion using the DLT data and some explicitly stated assumptions as to the physiology of the fetoplacental unit. The model, its mathematical representation, and computer program are described in detail elsewhere.[1, 9]

Statistical significance is determined by means of the Mann-Whitney U test,[7] as discussed previously.[2] This test permits statistical comparison without requiring that the groups tested follow a normal or Gaussian distribution.[7]

Results

Baseline serum estrogens segregated by Groups A, B, C, and D. For comparison, total serum estrogen values obtained (basal values during the DLT protocol) are analyzed by groups. Tables III and Table IV illustrate their values and the lack of intergroup differences. Fig. 1 illustrates these data graphically.

DHEA to estrogen conversion rate constant values as segregated by Groups A, B, C, and D. The distribution of DHEA to estrogen conversion rate constants by group is shown in Table V. Fig. 2 illustrates that Group A had conversion rate constants tightly clustered between 4.2×10^{-3}, and 8.5×10^{-3} (the units of the conversion rate constant, $min.^{-1}$, are deleted for brevity).

Table VII. Patients for special discussion, DHEA-to-estrogen conversion rate constant as described in Table I

Patient	*Group*	*Gestational age at test time (wk.)*	*DHEA-to-estrogen conversion rate constant*
G.C.A.	D	37	1.2×10^{-3} $min.^{-1}$
M.H.O.	D	38	1.9×10^{-3} $min.^{-1}$
J.R.O.	C	37	209.0×10^{-3} $min.^{-1}$
J.P.E.	B	33½	986.0×10^{-3} $min.^{-1}$
J.P.E.′	C	38	2.8×10^{-3} $min.^{-1}$
S.C.A.	B	32	0.7×10^{-3} $min.^{-1}$
S.C.A.′	D	34	4.9×10^{-3} $min.^{-1}$

Table VIII. Group E patients (see Table I)

Patient	*Group*	*Gestational age at test time (wk.)*	*DHEA-to-estrogen conversion rate constant*
V.F.R.	E	35	36.1×10^{-3} $min.^{-1}$
M.W.I.	E	36 + 1 wk. IUFD	4.5×10^{-3} $min.^{-1}$
M.W.I.′	E	36 + 2 wk. IUFD	3.0×10^{-3} $min.^{-1}$
J.A.N.	E	29 + 2 wk. IUFD	303.0×10^{-3} $min.^{-1}$
J.P.U.	E	Nonpregnant	0.04×10^{-3} $min.^{-1}$

Note that most patients who were delivered of normal babies (Groups A and D) had DHEA to estrogen conversion rate constants greater than 2.9×10^{-3}, while most patients with compromised fetuses had values of less than 2.9×10^{-3}. Table VI presents the statistical intergroup comparisons. Note that, while the DLT could not discriminate between the normal patients (Group A) and the high-risk, good-outcome patients (Group D), it was able to distinguish both groups from the high-risk patients whose infants showed signs of chronic placental insufficiency (Group B).

Miscellaneous Group E results. The Group E patients are excluded from the above analysis since they deserve special attention, and cannot be compared with the other patients. Since no definite conclusion can be obtained from this miscellaneous group of patients, all individuals will be discussed separately. Information pertaining to these patients plus other patients deserving discussion (two Group B patients, one Group C patient, two Group D patients) may be found in Tables VII and VIII. The possible physiopathologic implications are presented in the "Comment."

Comment

Our first report[5] demonstrated the capability of the animal fetoplacental unit model to convert DHEA to estrogens. The same study showed a lower conversion capability when the fetus was compromised. The previous data stimulated our group to try the exogenous administration of DHEA to the pregnant women in

order to develop a dynamic fetoplacental unit function test. Our first clinical report[2] clearly demonstrated that the application of a mathematical model of the DHEA to estrogen conversion data resulting in a DHEA to estrogen conversion rate constant was a reliable means of segregating a population of pregnant patients by pregnancy outcome. Although the number of tests and the number of patients was small (19), our results were able to distinguish with significance between normal pregnancies resulting in normally grown infants, high-risk pregnancies resulting in normally grown infants, and high-risk pregnancies resulting in infants showing signs of chronic placental insufficiency.

It was also interesting that no false positive or false negative results were found in that first study. In addition, and possibly because of the small numbers, the DLT could not distinguish between high-risk pregnancies resulting in chronically distressed infants, and those who, while normally grown, developed signs of acute fetal distress during labor. This lack of discrimination may be interpreted as reflecting different degrees of placental sufficiency.

The study of additional patients using the same protocol has again demonstrated that most patients (17 out of 19) who were delivered of normal infants (Groups A and D) had DHEA-to-estrogen conversion rate constants greater than 2.9×10^{-3}.

In contrast, the majority of patients (15 of 17) with compromised fetuses (Groups B and C) showed conversion rate constants of less than 2.9×10^{-3}. Fig. 2 graphically demonstrates the differences in DHEA to estrogen conversion rate constant distributions between these different groups. Table VI shows the significant differences between Groups A and B, Groups B and C, and Groups B and D. In marked contradistinction to these relationships are the intergroup differences in the baseline maternal serum estrogen concentrations. Fig. 1 shows the lack of any consistent intergroup differences in the baseline serum maternal estrogen concentrations and Table IV shows a significant difference in the baseline serum maternal estrogen concentration between groups A and C and Groups B and D. These differences are primarily due to the unusually high baseline serum maternal estrogen concentrations found in Group D, a phenomenon that we do not understand. It should be noted that there was no significant difference in the baseline maternal serum estrogen concentrations between Group A, the normal patients, and Group B, the high-risk patients who delivered infants with signs of chronic placental insufficiency. These data argue against the utilization of maternal serum estrogen concentration as a means of identifying patients at risk of delivering infants with signs of chronic placental insufficiency. This is not to negate the value of serial maternal serum estrogen concentration determinations in predicting pregnancy outcome.

There are seven DLT's in five patients set aside in Table VII that merit further discussion.

Patient G.C.A. of Group D had a markedly abnormal DHEA to estrogen conversion rate constant of 1.2×10^{-3} at 37 weeks' estimated gestational age (EGA). She was considered to be a high-risk obstetric patient because of habitual abortions and a history of toxemia, anemia, and pregnancy associated hypertension with premature labor and delivery on her sole previous successful pregnancy. Approximately one week after the DLT, she was delivered of a 3,000 gram infant with Apgar scores of 9 and 10. There were no signs of fetal distress during labor. Gross examination of the placenta revealed it to be clinically small with multiple calcifications and infarcts. Through an unfortunate oversight the placenta was neither weighed nor examined microscopically. It is of interest that the placental abnormalities (apparently picked up by the DLT) were insufficient to cause either significant growth retardation or fetal distress during labor. This must be considered a false positive DLT.

The other false positive result was obtained in patient M.H.O., who had a DHEA to estrogen conversion rate constant of 1.9×10^{-3} at 38 weeks' EGA. She was delivered of a 2,570 gram infant with Apgar scores of 7 and 9 after an uncomplicated labor and delivery without signs of fetal distress. A high-risk factor of suspected IUGR was noted at the time of the DLT; however, this was not substantiated by Lubchenco chart. We can provide no explanation for this false positive report.

One of the false negative results was obtained from Patient J.R.O. She had a conversion rate constant of 209×10^{-3} at 37 weeks' EGA, well above the normal range. Approximately three weeks later she was delivered of a 3,020 gram infant with Apgar scores of 8 and 10, showing alternating fetal bradycardia and tachycardia during labor. While it can be surmised that an insult occurred after the DLT, or that the distress in labor was not secondary to placental dysfunction, this must be considered a false negative test.

J.P.E was the second patient with a false negative test, but only if the strictest criteria are used. At 33½ weeks' EGA, with a cessation of fundal height growth for 6 weeks, she had a conversion rate constant of 986×10^{-3}, consistent with the group that were delivered of normally grown, nondistressed infants (Group D). Hence, this must be considered a definite false negative result. Because of her clinical IUGR she was placed on

strict bed rest for six weeks, in addition to a high-calorie and high-protein diet. She subsequently had a conversion rate constant of 2.8×10^{-3} at 38 weeks' EGA, showing a resumption of clinical fetal growth in the interim. She went on to be delivered of a 3,100 gram infant with Apgar scores of 8 and 9 approximately 1 week later, showing fetal bradycardia during labor. While the second DLT result was appropriate for the outcome, it is troublesome that the conversion rate constant showed such a dramatic fall in the presence of resumed fundal height growth. This result underscores our lack of understanding of both how well the conversion rate constant reflects placental function, and also of what causes intrauterine growth retardation. It is unfortunate that we do not have ultrasonographic documentation of lack of fetal growth in this case, even though the biparietal diameter seems to be the last parameter to change in IUGR when secondary to placental insufficiency.

A most interesting patient is S.C.A., whose conversion rate constant of 0.7×10^{-3} at 32 weeks' EGA was consistent with a noted lack of uterine growth for 5 weeks. A repeat DLT was done 2 weeks later, after strict bed rest and dietary therapy, revealing her conversion rate constant to be 4.9×10^{-3}, apparently reflecting success of the therapy. She later was delivered of a 4,040 gram infant with Apgar scores of 9 and 9 after an uncomplicated labor and delivery.

We now turn our attention to Group E, comprising five DLT's in four patients. These patients were not included in the above statistical analyses as it was impossible to place them in any of the previously described four groups. They are also included in Table VIII.

Patient V.F.R. had a higher than normal conversion rate constant of 36.1×10^{-3} at 35 weeks' EGA. Then at 35½ weeks' EGA she was delivered of a 900 gram infant with Apgar scores of 3 and 3, with multiple congenital abnormalities (bilateral complete cleft lip and palate, microcephaly, multiple ecchymoses). While this case may be looked upon as false negative, there was no evidence of placental insufficiency and her pregnancy outcome can be presumed to be explained by the observed fetal anomalies. Unfortunately, autopsy was refused by the family.

Patient M.W.I. had documented intrauterine fetal death at 36 weeks' gestation. DLT's were done 1 and 2 weeks later and showed essentially normal conversion rate constants of 4.5×10^{-3} and 3.0×10^{-3}, respectively. This reflects both the expected continuation of placental function after fetal death and the fact that the DLT is in no way a test of fetal function. It is difficult to draw a conclusion from the apparently falling conversion rate constant. She was delivered of a 2,460 gram stillborn infant on the day of the last DLT.

Yet another intrauterine fetal death was evaluated in Patient J.A.N., who had documented fetal death at 29 weeks' gestation. Two weeks later the conversion rate constant was found to be 303×10^{-3}. This result differs greatly from that of the previous patient for reasons that we cannot suggest with any firm basis in fact. We hypothesize that in the absence of basal circulating DHEA the ability of the placenta to convert DHEA to estrogen is markedly increased, at least temporarily. Further studies in patients receiving adrenal steroids, and in patients carrying anencephalic infants, may provide a better understanding.

The final DLT in Table VIII was on Patient J.P.U., a nonpregnant woman. Her conversion rate constant was 0.04×10^{-3} on Day 9 of the menstrual cycle. Unknown to us, on the day of testing, she was taking Synthroid, 0.1 mg per day, for uncomplicated hypothyroidism. While the latter fact renders her a less than perfect control subject, there is no reason to suspect that this would alter the results as she was clinically euthyroid.

The DHEA loading test continues to hold promise as a predictor of pregnancy outcome, ostensibly as a placental function test. However, before the DLT can be applied generally and used as a basis for clinical decisions, extensive testing must be done to further evaluate its diagnostic and possible predictive value in a larger number of normal pregnancies, as well as in pregnancies complicated by various maternal disease processes or poor reproductive histories. At present, there are sufficient data to strongly recommend further evaluation of utilization of DHEA to estrogen conversion dynamics in managing high-risk pregnancies.

Further studies in patients like those studied in Group E (experiments of nature) should provide a better understanding of placental DHEA metabolism.

The causal relationship between the use of lidocaine and fetal bradycardia and the effect of the drug on maternal and fetal hemodynamics were studied on 13 chronically instrumented pregnant sheep. Lidocaine was infused intravenously to the mother for 60 minutes during arterial lidocaine concentrations were maintained at 2 to 5 μg per milliliter in the mother and at less than 2 μg per milliliter in the fetus. A decrease in uterine blood flow and an increase in uterine vascular resistance and uterine activity occurred immediately following the administration of lidocaine to the ewe. These changes were followed by a transient fetal bradycardia in 12 out of 17 experiments, accompained by a decrease in fetal Pao_2 values. These phenomena were seen in the absence of such predisposing conditions as maternal hypotension and fetal acidosis. It would appear that the mechanism responsible for a transient fetal bradycardia following regional obstetric anesthesia, particularly paracervical block anesthesia, in the initially nonasphyxiated fetus may in part be related to a brief decrease in perfusion of intervillous spaces. The bradycardia can occur at low lidocaine concentrations in both the maternal and fetal blood in a range similar to that observed in clinical practice. (AM. J. OBSTET. GYNECOL. 134:289, 1979.)

THE MECHANISM underlying the transient fetal bradycardia occasionally seen in association with regional anesthesia, particularly paracervical block, in obstetrics has not been clearly understood, The paracervical block–induced fetal bradycardia has been attributed to a direct toxic effect of local anesthetic on the fetal myocardium, caused by drug absorbed from the highly vascular area of injection and transferred to the fetus.[1] This hypothesis was supported by the presence of significant levels of local anesthetics which were found in the fetal blood following paracervical block.[2–4] However, our previous animal studies have shown that high doses of local anesthetics given directly to the healthy fetal guinea pig or lamb are well tolerated.[5, 6] By contrast, when lidocaine was injected into the pregnant ewe, a transient fetal bradycardia was observed in association with a decrease in fetal cardiac output, umbilical blood flow, and uterine blood flow.[7] These changes occurred at relatively low drug concentration in the fetal blood. Recent in vitro studies have shown that high concentrations of local anesthetics have a vasoconstrictive effect on the uterine artery.[8–10] This vasoconstriction may result in a decrease of uteroplacental blood flow, fetal asphyxia, and bradycardia.[8]

the use of local anesthetics and fetal bradycardia, the effects of lidocaine on maternal and fetal hemodynamics have been studied.

Materials and methods

A total of 17 experiments were performed on 13 pregnant ewes at gestational ages ranging from 121 to 138 days. Initially the ewes were operated upon under spinal anesthesia with tetracaine, supplemented as necessary with thiopental. Catheters were placed in the femoral artery and vein of the ewe. Catheters were also placed in a carotid artery and internal jugular vein of the fetus through a small hysterotomy incision. A catheter was placed into the amniotic cavity through which intrauterine pressure could be measured and the uterus was closed. The estimated loss of amniotic fluid was replaced with an equal volume of normal saline. An electromagnetic blood flow probe (Micron Instruments, Inc., Los Angeles, Calif.) was applied to the main uterine artery of the pregnant horn, a catheter was inserted into a uterine vein, and the abdomen was closed. The catheters and blood flow probe leads were tunneled subcutaneously and placed in a pouch attached to the flank area of the ewe. The catheters were flushed and filled with heparinized saline solution daily. Experiments were performed in these animals from 2 to 18 days after the initial operation. A minimum of 48 hours was allowed to elapse between experiments to assure recovery of mother and fetus prior to the next observation.

During each study, the ewe was restrained in a cart. Arterial blood pressure and heart rate of both mother and fetus, as well as uterine venous and intrauterine pressures and uterine blood flow were measured and recorded continuously. The arterial pulse waves served as input for the cardiotachometer. Uterine vascular resistance was estimated by dividing the measured mean arterial pressure minus the uterine venous pressure by the uterine blood flow. Arterial blood samples were withdrawn simultaneously from mother and fetus prior to and during the experiment. Blood pH, Pco_2, and Po_2 values were measured with the use of Radiometer microelectrodes and a Radiometer gas analyzer. The base deficit was calculated with the use of the Radiometer blood gas calculator. Blood samples were also analyzed for lidocaine concentrations with a gas chromatographic technique.[11]

None of the mothers was in active spontaneous labor 1 to 2 hours prior to the initiation of the experiment. To examine the effect of increased uterine activity on the uterine blood flow and fetal hemodynamics, oxytocin at the rate of 20 to 30 mu per minute was infused intravenously to the mother in six experiments prior to the administration of lidocaine. The infusion was maintained during the entire course of the experiments. Uterine activity was expressed as Montevideo units (MVU).[12] In order to maintain lidocaine levels in the maternal arterial blood between 2 and 5 μg per milliliter and fetal blood between 1 and 2 μg per milliliter, lidocaine was infused into the maternal vein at the rate of 0.3 to 0.4 mg. per kilogram per minute for the initial 15 minutes, then decreased to 0.1 to 0.2 mg per kilogram per minute for the remaining 45 minutes. Observation was continued for an additional 30 minutes after the completion of lidocaine administration.

Comparisons of data between the period prior to infusion and during infusion of lidocaine were made with a paired t test. Correlations were estimated by linear regression curves.

Results

All mothers and fetuses had normal cardiovascular and acid-base state prior to the infusion of lidocaine (Table I).

Lidocaine concentrations in maternal and fetal blood during and after the intravenous infusion of the drug to the mother are depicted in Fig. 1. The drug levels in blood showed no differences between the group of animals which did and did not receive oxytocin, and the groups have therefore been combined. Maternal level of lidocaine reached approximately 4 μg. per milliliter after 5 minutes at the high rate of infusion; this

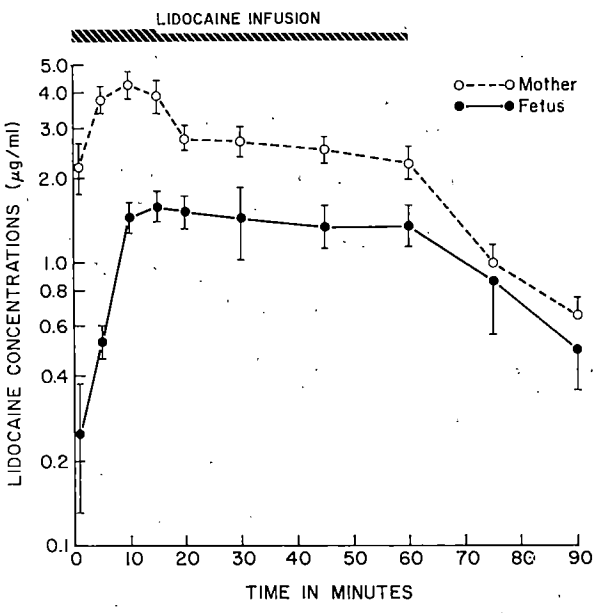

Fig. 1. Mean concentrations and standard error of the mean for lidocaine in arterial blood of the mother and fetus during and after intravenous infusion of lidocaine to the pregnant ewe. Lidocaine was infused at a rate of 0.3 to 0.4 mg. per kilogram per minute for 15 minutes, followed by a reduced rate of 0.1 to 0.2 mg. per kilogram per minute for 45 minutes in 17 experiments.

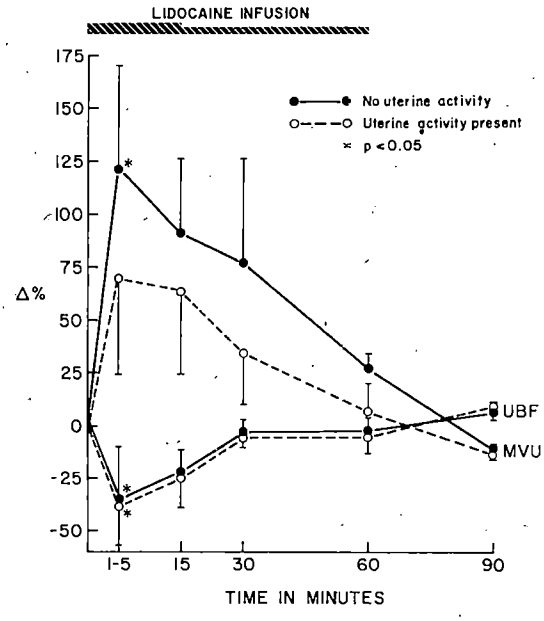

Fig. 2. Mean (S.E.) proportional changes in uterine activity *(MVU)* and uterine blood flow *(UBF)* during and after intravenous infusion of lidocaine to the pregnant ewe. Solid circles indicate animals exhibiting no uterine activity prior to lidocaine administration (N = 11); open circles represent animals in which uterine activity (oxytocin induced) was present before the start of the experiment (N = 6).

level remained steady until the rate was decreased. Following the decrease of the infusion rate, the drug concentration in the maternal blood remained between 2 and 3 μg per milliliter. The initial high rate of infusion brought the lidocaine concentration in the fetal blood up to a plateau of 1.4 to 1.6 μg per milliliter within 10 minutes. The levels remained between 1 and 2 μg per milliliter throughout the infusion.

The infusion of oxytocin in the maternal vein induced uterine contractions with a mean of 160 ± 58 (S.E.) MVU prior to the administration of lidocaine. This was accompanied by a 30 per cent decrease in uterine blood flow when compared to the preoxytocin value of 436 ± 45 ml. per minute. Uterine vascular resistance increased slightly from 0.399 ± 0.0156 to 1.007 ± 0.0381 mm. Hg per milliliter per minute. Prior to giving lidocaine an average of 30 units of oxytocin by infusion was necessary to establish a regular uterine contraction pattern in which the intra-amniotic pressure returned to nearly baseline tone during each contraction.

Proportional changes in uterine activity and uterine blood flow following the infusion of lidocaine are seen in Fig. 2. In 11 experiments where uterine activity was not augmented by oxytocin, the prelidocaine value of uterine blood flow was 392 ± 33 ml. per minute and uterine vascular resistance, 0.255 ± 0.0217 mm. Hg per milliliter per minute. A 122 ± 48 per cent ($P < 0.05$) increase in MVU, with a corresponding decrease of 35 ± 23 per cent ($P < 0.05$) uterine blood flow occurred immediately following the initiation of the infusion of lidocaine. The pattern of uterine contraction was rather tetanic; the resting tone remained elevated during the interval between uterine contractions. Uterine vascular resistance also increased significantly to 2.391 ± 0.892 mm. Hg per milliliter per minute. All six experiments receiving oxytocin prior to lidocaine infusion had an increase in MVU (69 ± 44 per cent) and decrease in uterine blood flow (39 ± 17 per cent) ($P < 0.05$), from the prelidocaine levels. Increase in MVU in this group was not statistically significant. The changes in MVU, uterine blood flow, and uterine vascular resistance were most profound during the first 10 minutes, with the subsequent return toward the preinfusion values, even though the infusion was continued for an additional 50 minutes.

Prelidocaine values of heart rate and arterial pressure in the mothers with or without induced uterine activity were similar. The effect of oxytocin-induced uterine contractions on the fetus was minimal; the heart rate tended to decrease from the preoxytocin level of 171 ± 6.0 to 165 ± 3.4 beats per minute prior to the infusion of lidocaine, but the change was not statistically significant. Initial fetal pHa and Pa_{O_2} were 7.36 ± 0.01 and 24 ± 1.0 mm. hg without oxytocin and 7.36 ± 0.02 and 22 ± 0.8 mm. Hg with oxytocin, re-

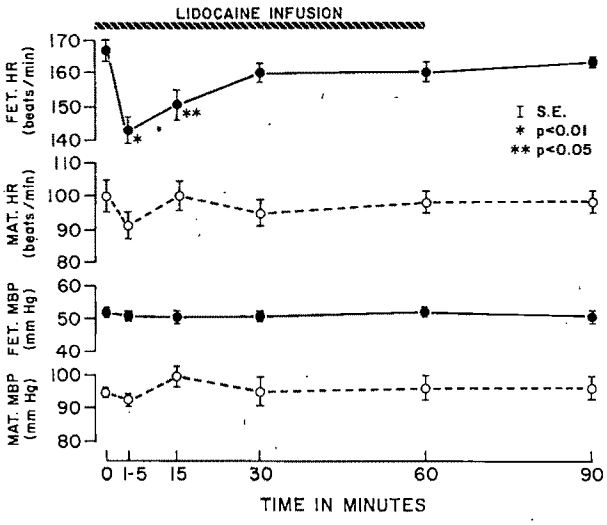

Fig. 3. Changes in the fetal and maternal heart rate and fetal and maternal mean arterial pressure during and after the infusion of lidocaine to the mother. Values are mean ± S.E.; n = 17.

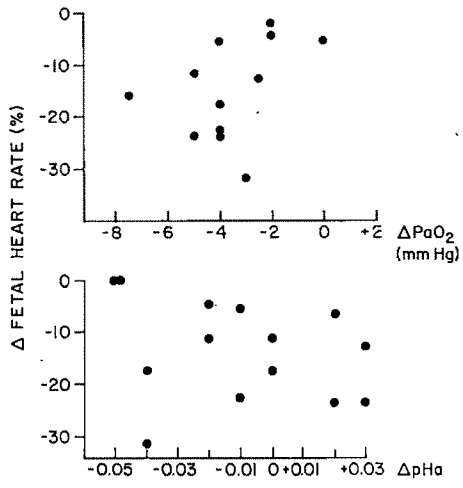

Fig. 4. Relationships between the degree of fetal bradycardia and change in fetal Pa_{O_2} or pHa.

spectively. Therefore all values were combined, regardless of presence or obsence of uterine contractions. Changes in fetal and maternal heart rate and fetal and maternal arterial pressure during and after completion of lidocaine infusion to the mother in 17 experiments are seen in Fig. 3. A significant but transient decrease in fetal heart rate occurred in 12 out of 17 experiments from the preinfusion value of 167 ± 5.7 to 142 ± 4.4 beats per minute ($P < 0.01$), beginning with the first 5 minutes of the infusion and lasting for 15 minutes. In the remaining five, heart rate either did not change or increased slightly. There was no significant change in fetal arterial pressure. Maternal heart rate and blood pressure remained essentially unchanged during the infusion of lidocaine. Blood samples obtained when fetal bradycardia was maximal (during the first 15 minutes) revealed a decreased Pa_{O_2} in all but one of the fetuses (Fig. 4), from a mean preinfusion value of 23 ± 1.0 to 19 ± 1.2 mm. Hg ($P < 0.01$). However, no correlation between the degree of bradycardia and decrease in Pa_{O_2} was found, the correlation coefficient being 0.209; the normal distribution of decreased fetal heart rate and Pa_{O_2} were statistically indistinguishable. The decreased Pa_{O_2} values were only transient; recovery had occurred by the time the next sample was obtained, 5 to 15 minutes after an episode of bradycardia. Pa_{O_2} values remained unchanged in five fetuses in which the heart rate did not change during lidocaine infusion. There was no distinct correlation between fetal bradycardia and changes in fetal pHa (Fig. 4). Fetal Pa_{CO_2} and base deficit values also did not change during bradycardia. The acid-base state of mother as well as fetus remained essentially unchanged throughout the entire observation period (Table I).

A typical recording of the mean uterine blood flow, the intra-amniotic pressure, the heart rate and arterial pressure of the fetus, and those of the mother is presented in Fig. 5. This ewe received the infusion of lidocaine at the initial rate of 0.3 mg. per kilogram per minute for 15 minutes, followed by 0.1 mg. per kilogram per minute. The preinfusion value of the fetal pHa was 7.40; Pa_{CO_2}, 36 mm. Hg; base deficit, 2.0 mEq. per liter; and Pa_{O_2}, 24 mm. Hg. A transient decrease in uterine blood flow from the preinfusion value of 300 ml. per minute to approximately 40 ml. per minute and a marked increase in uterine vascular resistance from 0.252 to 1.783 mm. Hg per milliliter per minute occurred in 2 to 3 minutes after the infusion had begun. This was followed by an increase in uterine activity, with raised intra-amniotic pressure from the preinfusion value of 7 to an average peak of 25 mm. Hg, and frequency of contraction from 0 to 29 per minute respectively. Initial fetal heart rate was 150 beats per minute, but it began to decrease after 5 to 6 minutes of the infusion and became 140 beats per minute after uterine activity and blood flow had begun to recover following 10 minutes of infusion. However, decreased heart rate did not persist longer than 20 minutes; at 25 minutes it had returned to the initial level. Fetal Pa_{O_2} also fell from 24 to 21 mm. Hg, although it was only transient. Lidocaine concentration in the fetal blood was less than 2 μg per milliliter; in the maternal blood it was less than 5 μg per milliliter throughout the infusion. The effect of lidocaine in the presence of oxytocin-augmented contractions is illustrated in Fig. 6. There was an abrupt and marked reduction in uterine blood flow, from 425 to 60 ml. per minute, and an

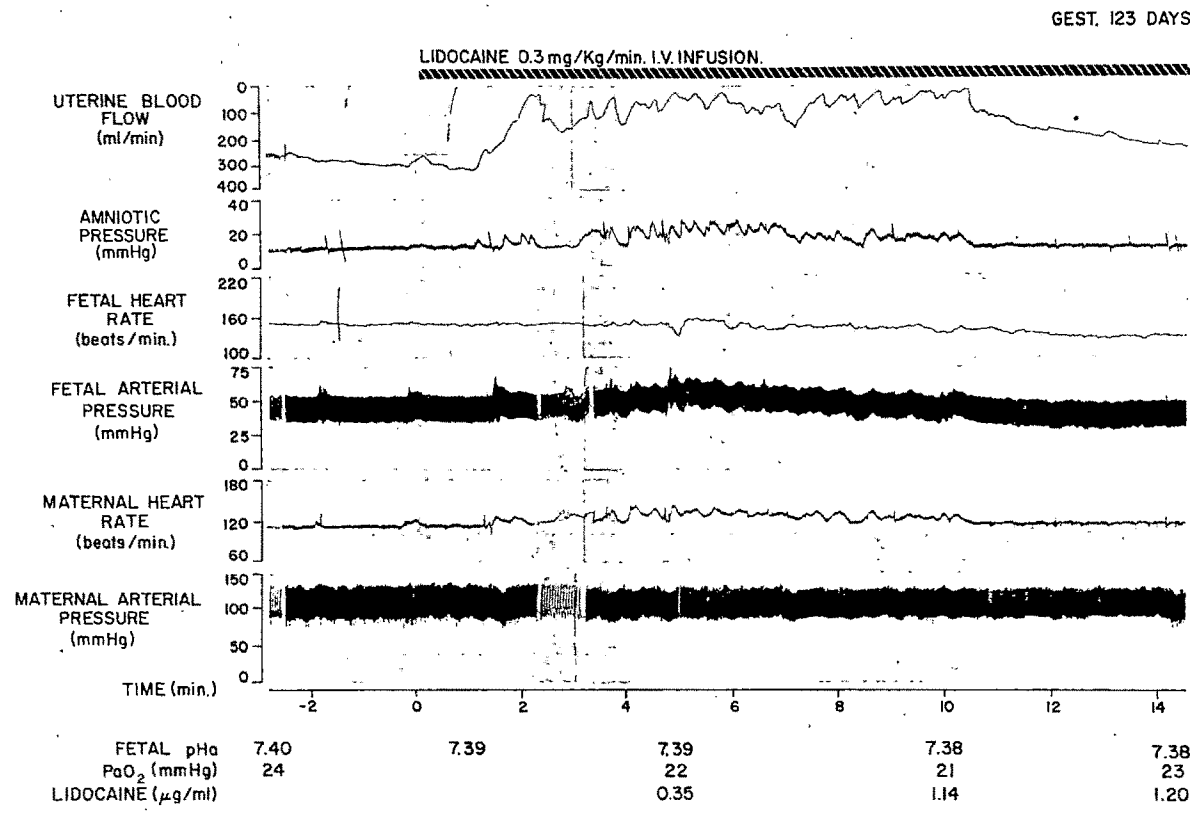

Fig. 5. A typical recording of the mean uterine blood flow, the intra-amniotic pressure, the heart rate and arterial pressure of the fetus, and those of the mother during the infusion of lidocaine at the initial rate of 0.3 mg. per kilogram per minute. Note that the direction of the curve is inverted in the tracing of the uterine blood flow. The upward swing denotes a decrease and a downward swing denotes an increase. The fetal pHa, Pa_{O_2}, and arterial lidocaine levels are shown in the lower space.

increase in vascular resistance from 0.357 to 2.725 mm. Hg per milliliter per minute which corresponded to a rise in uterine activity of approximately 160 MVU from the preinfusion value of 70 MVU. These changes were maintained for 11 minutes, then began to return toward preinfusion values, while lidocaine infusion was continuing. In this experiment the fetal bradycardia occurred earlier (from the initial value of 160 to 120 beats per minute) which was preceded by tachycardia (180 beats per minute). Decreased heart rate was associated with decreased fetal Pa_{O_2} from 24 to 21 mm. Hg. The maternal lidocaine levels ranged between 2.5 and 3.6 μg per milliliter, with fetal levels less than 2 μg per milliliter.

Comment

This study indicates that transient bradycardia, occasionally seen in association with obstetric regional anesthesia, particularly paracervical block, may in part be related to decreased fetal Pa_{O_2} secondary to a reduction in uteroplacental blood flow, an increase in uterine vascular resistance, and an increase in uterine activity. The cause of bradycardia cannot be due only to an elevated drug level in the fetal blood, since the above phenomena can occur at low lidocaine concentrations in both the maternal and fetal blood in a range similar to that observed in clinical practice. The bradycardia can also be induced in the absence of such predisposing conditions as maternal hypotension and fetal acidosis. Therefore, the conclusive etiology of this fetal bradycardia still remains unclear. Following paracervical block, high local anesthetic concentrations have been found in human fetal blood which appear to correlate with the occurrence of fetal acidosis, bradycardia, and subsequent depression at birth,[1–4] which is suggestive of a direct toxic effect of the local anesthetic drug on the human fetal myocardium. Other animal and human studies failed to support this hypothesis. For example, experiments in sheep have shown that the intravenous infusion of lidocaine or etidocaine in the toxic dose to the adult does not produce cardiac depression in the nonasphyxiated fetus,[6, 13] whereas transient decrease in fetal heart rate was observed when lidocaine was infused into the mother in a dose which pro-

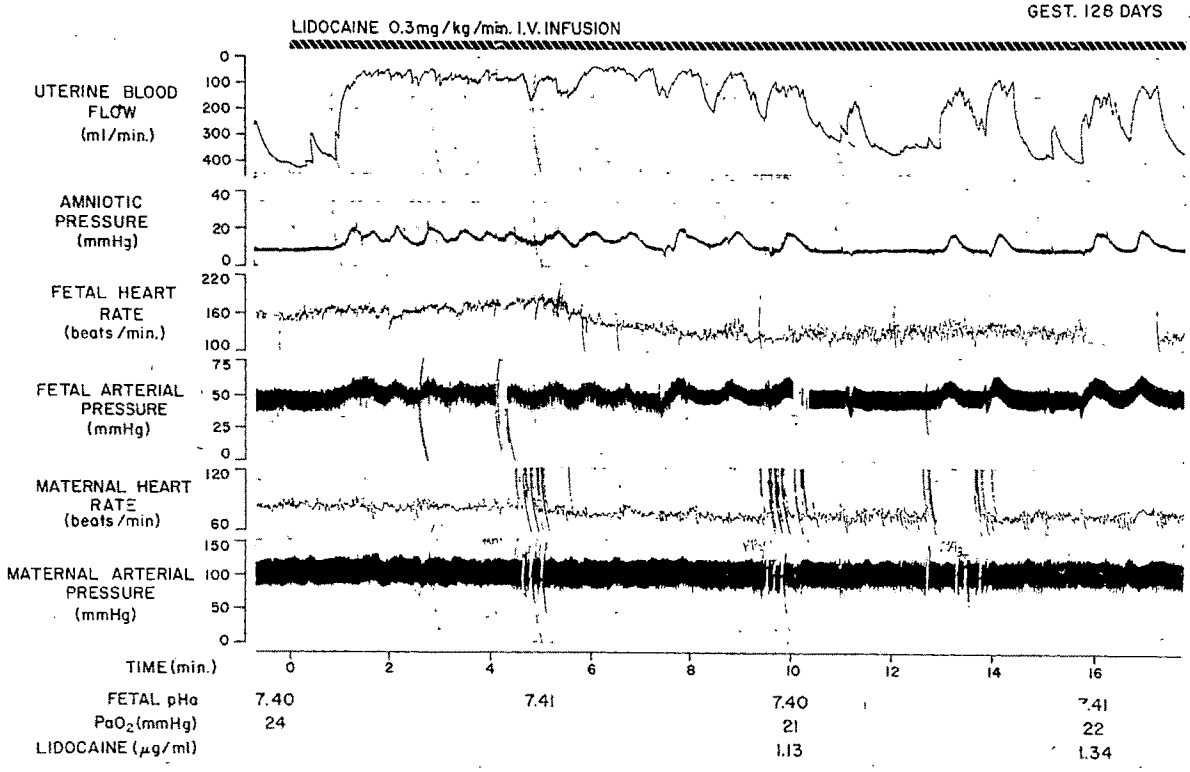

Fig. 6. The effect of lidocaine on the mean uterine blood flow, the intra-amniotic pressure, the heart rate and arterial blood pressure of the fetus, and those of the mother during established regular uterine contractions, induced by oxytocin. Fetal bradycardia occurred earlier and was more profound than those seen in animals not in labor. Note that the direction of the curve is inverted in the tracing of the uterine blood flow. The upward swing denotes a decrease and a downward swing denotes an increase. The fetal pHa, Pa_{O_2}, and arterial lidocaine levels are present in the lower space.

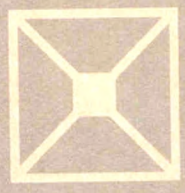
duced a relatively low level of the drug in fetal blood.[7] These studies suggested that a fall in fetal heart rate observed was related more to a decrease in umbilical uterine blood flow than to direct toxic effect of the local anesthetic on the fetal myocardium. Human fetal electrocardiographic studies are also not consistent with a direct toxic effect of anesthetics on the myocardium[14]; the fetal bradycardia observed following paracervical block with mepivacaine was not associated with any signs of conduction defects, whereas the intentional administration of massive doses of mepivacaine directly into anencephalic fetuses showed signs of conduction impairment as seen in studies of adults with toxicity.

In the present study, transient uterine vasoconstriction was observed immediately following the initiation of lidocaine infusion into the maternal vein. This vasoconstrictor effect persisted for approximately 15 minutes, during which time a decrease in fetal Pa_{O_2} value and heart rate was observed. A fall in heart rate could not be related to a direct cardiac effect of lidocaine, since the fall was only transient in nature, while the fetal lidocaine blood concentration remained low at a level of 1 to 2 μg per milliliter. It is more likely that the decrease in Pa_{O_2} value and the fetal heart rate are causally related to the decrease in uterine blood flow, since the fetal Pa_{O_2} and fetal heart rate returned to their normal levels when the uterine blood flow and uterine activity returned toward the preinfusion values. The uterine vasoconstrictor effect of lidocaine has recently been observed by Greiss, Still, and Anderson[8] following the intravascular administration of local anesthetics to pregnant and nonpregnant ewes, the uterine blood flow was reduced. These authors also reported that the reduced uterine blood flow tended to return toward preinfusion values while lidocaine was still being infused. The transient uterine vasoconstrictor action of lidocaine observed in this and other studies may be related to the biphasic vascular effect of local anesthetics reported by other authors. For example, Blair[15] has reported an increase in the myogenic activity of isolated rat portal vein following exposure to low con-

centrations of various local anesthetics. This was followed by a subsequent relaxation of vascular smooth muscle at higher concentrations of local anesthetic. Similar findings have also been reported in man by Jorfeldt and associates.[16] Thus, the uterine vasoconstriction observed immediately following infusion of lidocaine may reflect the stimulatory action of local anesthetics on vascular smooth muscle.

Local anesthetics, when presented to the myometrium in high concentrations, have an oxytocic effect. McGaughey and associates[17] studied the effects of various local anesthetics on isolated pregnant and nonpregnant human myometrium. All the tested drugs increased contraction amplitude and/or baseline tone. Procaine injected into the term human pregnant uterus produced marked hypercontractility.[18] Intravenous injection of lidocaine in patients during labor also increased uterine activity when the drug levels in venous blood ranged between 4 and 7 μg per milliliter.[19] A transient increase in uterine activity accompanied by fetal bradycardia has been reported in 24 out of 92 patients who received paracervical block with mepivacaine.[14] Although both oxytocin and lidocaine increased uterine contractility and decreased uterine blood flow in the present study, the decrease in fetal heart rate and Pa_{O_2} value was significant only during lidocaine administration. Under normal circumstances the oxygen store in the fetal blood and in the intervillous space is more than sufficient to maintain fetal oxygenation during uterine contractions. However, the pattern of contraction produced by lidocaine was more tetanic and persistent, and the increase in uterine vascular resistance was more marked than during oxytocin administration. Therefore, in the presence of lidocaine the interval between uterine contractions was probably not adequate to allow a complete restoration of fetal blood flow and oxygenation prior to the forthcoming contractions. Although decrease in fetal Pa_{O_2} in the human has not been reported during the fetal bradycardia associated with paracervical block, the presence of metabolic acidosis, as indicated by a significant fall in scalp pH and a rise in base deficit,[1, 14] is suggestive of diminished fetal oxygenation. The absence of acidosis in our animals in the presence of a transient fall in Pa_{O_2} is most likely due to the fact that the duration of decreased Pa_{O_2} was not long enough to allow for the development of metabolic acidosis.



Our results would suggest that the transient fetal bradycardia observed is probably not of great clinical significance in the normal fetus. However, we feel it is important to discuss the possibility of a direct depressant effect of local anesthetics if the fetus is already acidotic and hypoxemic. Since cardiovascular response to local anesthetics has been shown to be more pronounced at low pH and oxygen, the drug levels which are tolerated well by the nonasphyxiated fetus might cause myocardial depression in the asphyxiated fetus.[7] A reduction of umbilical blood flow or cardiac output itself would decrease the clearance of local anesthetic and may accumulate the drug in the fetus. Futhermore, removal of the local anesthetic from the asphyxiated fetus is not as efficient as in the unstressed fetus. Local anesthetics are transferred across the placenta in a nonionized form as weak bases. These drugs will accumulate on the lower pH side of membranes. Therefore, once the drug is transferred to the acidotic fetus, it tends to be trapped in the fetus. Indeed, lidocaine concentrations in the asphyxiated fetal lamb exceeded that in the mother following a single intravenous injection of the drug to the ewe.[7] In contrast, the lidocaine concentration in the nonasphyxiated fetal lamb fell rapidly and paralleled the decrease in drug concentrations in the maternal blood. Brown, Bell, and Alper[20] reported elevated fetal-to-maternal ratios of local anesthetics in four neonates with a low pH in the umbilical venous blood whose mothers received epidural anesthesia with lidocaine or mepivacaine. Thus, the mechanisms responsible for fetal bradycardia following regional obstetric anesthesia in the healthy and depressed fetus may be different.

Introducing a new antineoplastic agent.

PLATINOL™ cisplatin

Cisplatin (*cis*-diamminedichloroplatinum [DDP]), is now commercially available from Bristol Laboratories.

Initially recommended in established combination chemotherapy of metastatic testicular and ovarian tumors and, as a single agent, as secondary therapy for refractory metastatic ovarian tumors, PLATINOL (cisplatin) is supplied in 10 mg. amber vials.

SEE REVERSE SIDE FOR FULL PRESCRIBING INFORMATION.

For further information on Platinol™ (cisplatin), please complete this coupon and mail to:

To your reference, *complete* prescribing information for this important new product is presented.

3070DIM-02 8/78

WARNING Platinol (cisplatin) should be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Cumulative renal toxicity associated with Platinol is severe. Other major dose-related toxicities are myelosuppression and nausea and vomiting.

Ototoxicity, which may be more pronounced in children, and is manifested by tinnitus, and/or loss of high frequency hearing and occasionally deafness, is significant.

Anaphylactic-like reactions to Platinol have been reported. Facial edema, bronchoconstriction, tachycardia, and hypotension may occur within minutes of Platinol administration. Epinephrine, corticosteroids, and antihistamines have been effectively employed to alleviate symptoms (see "Warnings" and "Adverse Reactions" sections).

DESCRIPTION Platinol (cisplatin) (cis-diamminedichloroplatinum) is a heavy metal complex containing a central atom of platinum surrounded by two chloride atoms and two ammonia molecules in the cis position. It is a white lyophilized powder with the molecular formula $Pt\,Cl_2H_6N_2$, and a molecular weight of 300.1. It is soluble in water or saline at 1 mg/ml and in dimethylformamide at 24 mg/ml. It has a melting point of 207°C.

ACTION Platinol has biochemical properties similar to that of bifunctional alkylating agents producing interstrand and intrastrand crosslinks in DNA. It is apparently cell-cycle non-specific. Following a single I.V. dose, Platinol concentrates in liver, kidneys and large and small intestines in animals and humans. Platinol apparently has poor penetration into the CNS.

Plasma levels of radioactivity decay in a biphasic manner after an I.V. bolus dose of radioactive Platinol to patients. The initial plasma half-life is 25 to 49 minutes, and the post-distribution plasma half-life is 58 to 73 hours. During the post-distribution phase, greater than 90% of the radioactivity in the blood is protein bound. Platinol is excreted primarily in the urine. However, urinary excretion is incomplete with only 27 to 43% of the radioactivity being excreted within the first 5 days post-dose in human beings. There are insufficient data to determine whether biliary or intestinal excretion occurs.

INDICATIONS Platinol is indicated as palliative therapy to be employed as follows:

Metastatic Testicular Tumors—in established combination therapy with other approved chemotherapeutic agents in patients with metastatic testicular tumors who have already received appropriate surgical and/or radiotherapeutic procedures. An established combination therapy consists of Platinol, Blenoxane (Bleomycin Sulfate) and Velban (Vinblastine Sulfate).

Metastatic Ovarian Tumors—in established combination therapy with other approved chemotherapeutic agents in patients with metastatic ovarian tumors who have already received appropriate surgical and/or radiotherapeutic procedures. An established combination consists of Platinol and Adriamycin (Doxorubicin Hydrochloride). Platinol, as a single agent, is indicated as secondary therapy in patients with metastatic ovarian tumors refractory to standard chemotherapy who have not previously received Platinol therapy.

CONTRAINDICATIONS Platinol is contraindicated in patients with preexisting renal impairment. Platinol should not be employed in myelosuppressed patients, or patients with hearing impairment.

Platinol is contraindicated in patients with a history of allergic reactions to Platinol or other platinum-containing compounds.

WARNINGS Platinol produces cumulative nephrotoxicity. The serum creatinine, BUN, and creatinine clearance should be measured prior to initiating therapy, and prior to each subsequent course. At the recommended dosage, Platinol should not be given more frequently than once every 3 to 4 weeks (see "Adverse Reactions").

Anaphylactic-like reactions to Platinol have been reported. These reactions have occurred within minutes of administration to patients with prior exposure to Platinol, and have been alleviated by administration of epinephrine, corticosteroids and antihistamines.

Since ototoxicity or Platinol is cumulative, audiometric testing should be performed prior to initiating therapy and prior to each subsequent dose of drug (see "Adverse Reactions").

Safe use in human pregnancy has not been established. Platinol is mutagenic in bacteria and produces chromosome aberrations in animal cells in tissue culture. In mice Platinol is teratogenic and embryotoxic.

Platinol has not been studied for its carcinogenic potential but compounds with similar mechanisms of action and mutagenicity have been reported to be carcinogenic.

PRECAUTIONS Peripheral blood counts should be monitored weekly. Liver function should be monitored periodically. Neurologic examination should also be performed regularly (see "Adverse Reactions").

ADVERSE REACTIONS **Nephrotoxicity** Dose-related and cumulative renal insufficiency is the major dose-limiting toxicity of Platinol. Renal toxicity has been noted in 28 to 36% of patients treated with a single dose of 50 mg/M^2. It is first noted during the second week after a dose and is manifested by elevations in BUN and creatinine, serum uric acid and/or a decrease in creatinine clearance. **Renal toxicity becomes more prolonged and severe with repeated courses of the drug. Renal function must return to normal before another dose of Platinol can be given.**

Impairment of renal function has been associated with renal tubular damage. The administration of Platinol using a 6- to 8-hour infusion with intravenous hydration, and mannitol has been used to reduce nephrotoxicity. However, renal toxicity still can occur after utilization of these procedures.

Ototoxicity Ototoxicity has been observed in up to 31% of patients treated with a single dose of Platinol 50 mg/M^2, and is manifested by tinnitus and/or hearing loss in the high frequency range (4,000 to 8,000 Hz). Decreased ability to hear normal conversational tones may occur occasionally. Ototoxic effects may be more severe in children receiving Platinol. Hearing loss can be unilateral or bilateral and tends to become more frequent and severe with repeated doses. It is unclear whether Platinol-induced ototoxicity is reversible. Careful monitoring of audiometry should be performed prior to initiation of therapy and prior to subsequent doses of Platinol.

Hematologic Myelosuppression occurs in 25 to 30% of patients treated with Platinol. The nadirs in circulating platelets and leukocytes occur between day 18 to 23 (range 7.5 to 45) with most patients recovering by day 39 (range 13 to 62). Leukopenia and thrombocytopenia are more pronounced at higher doses (>50 mg/M^2). Anemia (decrease of >2 g hemoglobin/100 ml) occurs at approximately the same frequency and with the same timing as leukopenia and thrombocytopenia.

Gastrointestinal Marked nausea and vomiting occur in almost all patients treated with Platinol, and are occasionally so severe that the drug must be discontinued. Nausea and vomiting usually begin within one to four hours after treatment and last up to 24 hours. Various degrees of nausea and anorexia may persist for up to one week after treatment.

OTHER TOXICITIES **Hyperuricemia** Hyperuricemia has been reported to occur at approximately the same frequency as the increases in BUN and serum creatinine. It is more pronounced after doses greater than 50 mg/M^2, and peak levels of uric acid generally occur between 3 to 5 days after the dose. Allopurinol therapy for hyperuricemia effectively reduces uric acid levels.

Neurotoxicity Neurotoxicity, usually characterized by peripheral neuropathies, has occurred in some patients. Loss of taste and seizures have also been reported. Neuropathies resulting from Platinol treatment may occur after prolonged therapy (4 to 7 months); however, neurologic symptoms have been reported to occur after a single dose.

Platinol therapy should be discontinued when the symptoms are first observed. Preliminary evidence suggests peripheral neuropathy may be irreversible in some patients.

Anaphylactic-like Reactions Anaphylactic-like reactions have been occasionally reported in patients previously exposed to Platinol. The reactions consist of facial edema, wheezing, tachycardia and hypotension within a few minutes of drug administration. Reactions may be controlled by intravenous epinephrine, corticosteroids or antihistamines. Patients receiving Platinol should be observed carefully for possible anaphylactic-like reactions and supportive equipment and medication should be available to treat such a complication.

Other toxicities reported to occur infrequently are cardiac abnormalities, anorexia and elevated SGOT.

DOSAGE AND ADMINISTRATION **Metastatic Testicular Tumors**—An effective combination for the treatment of patients with metastatic testicular carcinomas includes Platinol, Blenoxane (Bleomycin Sulfate) and Velban (Vinblastine Sulfate). Remission induction therapy consists of Platinol, Blenoxane (Bleomycin Sulfate) and Velban (Vinblastine Sulfate) in the following doses:

PLATINOL—20 mg/M^2 I.V. daily for 5 days (days 1-5) every three weeks for three courses.

BLENOXANE® (Bleomycin Sulfate)—30 units I.V. weekly (Day 2 of each week) for 12 consecutive doses.

VELBAN® (Vinblastine Sulfate)—0.15 to 0.2 mg/kg I.V. twice weekly (Days 1 and 2) every three weeks for four courses (a total of eight doses).

Maintenance therapy for patients who respond to the above regimen consists of Velban (Vinblastine Sulfate) 0.3 mg/kg I.V. every 4 weeks for a total of 2 years.

For directions for the administration of Blenoxane (Bleomycin Sulfate) and Velban (Vinblastine Sulfate), refer to their respective package insert.

Metastatic Ovarian Tumors—An effective combination for the treatment of patients with metastatic ovarian tumors includes Platinol and Adriamycin (Doxorubicin Hydrochloride) in the following doses:

PLATINOL—50 mg/M^2 I.V. once every 3 weeks (Day 1).

ADRIAMYCIN™ (Doxorubicin Hydrochloride)—50 mg/M^2 I.V. once every 3 weeks (Day 1).

For directions for the administration of Adriamycin (Doxorubicin Hydrochloride), refer to the Adriamycin (Doxorubicin Hydrochloride) package insert.

In combination therapy, Platinol and Adriamycin (Doxorubicin Hydrochloride) are administered sequentially.

As a single agent, Platinol should be administered at a dose of 100 mg/M^2 I.V. once every 4 weeks.

Pretreatment hydration with 1 to 2 liters of fluid infused for 8 to 12 hours prior to a Platinol dose is recommended. The drug is then diluted in 2 liters of 5% Dextrose in ½ or ⅓N Saline containing 37.5 g of mannitol, and infused over a 6- to 8-hour period. Adequate hydration and urinary output must be maintained during the following 24 hours.

A repeat course of Platinol should not be given until the serum creatinine is below 1.5 mg/100 ml, and/or the BUN is below 25 mg/100 ml. A repeat course should not be given until circulating blood elements are at an acceptable level (platelets ≥100,000/mm^3, WBC ≥4,000/mm^3). Subsequent doses of Platinol should not be given until an audiometric analysis indicates that auditory acuity is within normal limits.

PREPARATION OF INTRAVENOUS SOLUTIONS Dissolve Platinol with 10 ml. of Sterile Water for Injection, U.S.P. Each ml of the resulting solution will contain 1 mg of Platinol.

Reconstitution as recommended results in a clear, colorless solution.

The reconstituted solution should be used intravenously only and should be administered by I.V. infusion over a 6- to 8-hour period. (See Dosage and Administration).

STABILITY Unopened vials of the dry powder must be stored in a refrigerator (2°C to 8°C). The recommended storage of unopened vials provides a stable product for 2 years.

The reconstituted solution is stable for 20 hours at room temperature (27°C).

Important Note: Once reconstituted, the solution should be kept at room temperature (27°C). If the reconstituted solution is refrigerated a precipitate will form.

SUPPLY PLATINOL (cisplatin) for Injection

NDC 0015-3070-20—Each amber vial contains 10 mg of cisplatin

PLATINOL™ cisplatin

CHARLES C THOMAS • PUBLISHER

MATERNAL NUTRITION AND CHILD HEALTH

By **Douglas R. Shanklin,** *Univ. of Chicago, and* **Jay Hodin,** *Society for the Protection of the Unborn Through Nutrition, both of Chicago. Foreword by* **S. L. Manocha.** This monograph brings together and summarizes an enormous body of information that supports the thesis that good quality protein and calorie nutrition with an abundance of salt and other available nutrients lies at the very root of a successful pregnancy. A relationship between nutritional factors and the entire spectrum of reproductive loss is also noted and substantiated.

Sections I through III of this book detail the effect of starvation on reproductive casualty, the effect of nutrition on birth weight, the relationship of low umbilical cord protein level to the development of respiratory distress syndrome, prospective and retrospective studies of effects of maternal nutrition, and the Vanderbilt cooperative study.

The physiological effects of malnutrition in correlation with impaired brain development and placental pathology are covered in Section IV. Also discussed are consequences of sodium deficiency, pathogenesis of metabolic toxemia of late pregnancy, and less direct evidence of pernicious effects of malnutrition.

Sections V through VIII explore the causal relationship between birth weight and prenatal nutrition, the association of mental deficiency with low birth weight and neurological damage and mental deficiency, interracial differences in reproductive causality, and the relation of maternal health to infant health and development. Maternal complications, the significance of prepregnancy weight and weight gain during pregnancy, and the effects of nutrition during infancy and early childhood are included.

Section IX presents a summary and conclusion of the scientific data introduced in this text.

The authors have done an excellent job of collecting and compiling pertinent information on the nutrition of the pregnant woman and its influence on her offspring. Numerous tables and other reference materials will permit this book to be used as a point of departure for further clinical and research studies. Obstetricians will find this volume extremely informative. *'79, 224 pp., 9 il., 68 tables, $14.75*

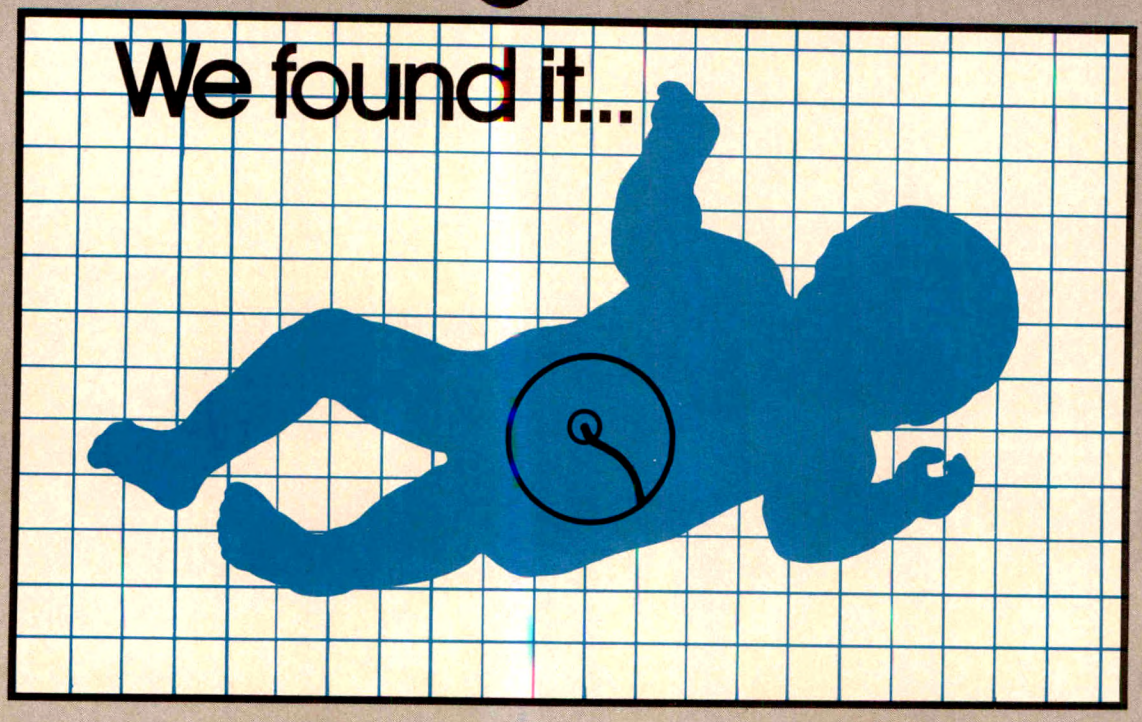
FEMALE URINARY STRESS INCONTINENCE *edited by* **Edward B. Cantor,** *Cedars-Sinai Medical Center, Los Angeles. Foreword by* **C. Paul Hodgkinson.** *(16 Contributors)* Sixteen urologists and gynecologists of international repute have collaborated to produce this comprehensive look at female urinary stress incontinence. Their contributions cover the latest theoretical and practical aspects of neuroanatomy, physiology and urodynamics. Chapters discuss the supports of the urethra, the role of the pubourethral ligaments in maintaining urinary continence, the detrusor dyssynergia syndrome, the electronic vaginal pessary, and the sling operation. Also presented is an optimal method of classifying and describing the exact degree of the anatomical defects involved in inadequate pelvic supports. *'79, 360 pp., 175 il., 19 tables, $27.50*

PRENATAL PATHOLOGY: Fetal Medicine *by* **T. V. N. Persaud,** *Univ. of Manitoba, Winnipeg, Manitoba, Canada, in collaboration with* **M. Ray** *and* **H. Rigatto.** *Foreword by* **T. M. Roulston.** This treatise offers up-to-date information on reproductive physiology, embryogenesis, fetal development, and maternal-fetal relationships. The pathophysiology of the conceptus, underlying causes of congenital malformations, genetics of developmental defects, common fetal disorders, and intrauterine diagnosis and management of congenital abnormalities receive equally thorough coverage. Informative tables, lucid illustrations and a thorough bibliography complement the text. *'79, 212 pp., 76 il., 31 tables, $23.00*

COLPOSCOPY: A Scientific and Practical Approach to the Cervix and Vagina in Health and Disease (2nd Ed.) *by* **Malcolm Coppleson,** *King George V Memorial Hospital, Sydney, Australia;* **Ellis Pixley,** *King Edward Memorial Hospital, Perth, Australia; and* **Bevan Reid,** *Univ. of Sydney, Sydney, Australia. (5 Contributors)* This completely rewritten and updated Second Edition continues to offer the reader an unsurpassed account of all aspects of the practice of colposcopy. Discussions focus on the topography of the cervical epithelia, the natural history of squamous metaplasia and the transformation zone, and tissue basis of colposcopic appearances. *'78, 512 pp. (6 3/4 x 9 3/4), 306 il. (1 in color), 11 tables, $36.50*

BIOKINETICS AND BIODYNAMICS OF HUMAN DIFFERENTIATION: Principles and Applications *by* **E. Blechschmidt,** *Univ. of Gottingen, Gottingen, West Germany, and* **R. F. Gasser,** *Louisiana State Univ., New Orleans.* Offering a revolutionary approach to human differentiation, this study views the developing embryo as a single unit, not as a number of isolated parts as has traditionally been the case. The first section considers early metabolic fields and includes chapters on the one-cell human ovum, the early embryo, blood vessels, the nervous sytem, head region, trunk and limbs. The second section, devoted to metabolic fields in later developmental stages, distinguishes corrosion, densation, contrusion, distusion, retention, dilation, liquation and detraction fields. *'78, 304 pp., 167 il., $28.25*

GENITOURINARY PROBLEMS IN WOMEN *by* **Jack R. Robertson,** *Univ. of Southern California Medical Center, Los Angeles. Foreword by* **Richard W. TeLinde.** This profusely illustrated text takes advantage of the endoscopic and other advances of the recent past to present a thorough review of the state of the art in treatment of such disorders. After a historical review of gynecological urology, the author delves into the anatomy and physiology of the female genitourinary tract, and explains methods of evaluation of urinary incontinence. Later chapters include vesicovaginal fistulae, urinary tract infections, the dysfunctional bladder and urethra, and pelvic surgery with endoscopic control. *'78, 168 pp., 105 il. (32 in color), 2 tables, $18.50*



PHYSICIANS' HANDBOOK OF NUTRITIONAL SCIENCE (4th Ptg.) *by* **Roger J. Williams,** *Univ. of Texas, Austin. Foreword by* **I. Newton Kugelmass.** The author provides a straightforward, readable account of the crucial meaning of nutrition and its importance in medical practice. In the few instances where he speculates or voices his opinion, the difference between fact and opinion is made evident. The main purpose of this text is to present facts from which the physician can draw his or her own deductions. Some of the topics considered are prenatal nutrition, internal nutrition and biochemical individuality. *'78, 128 pp., $11.50*

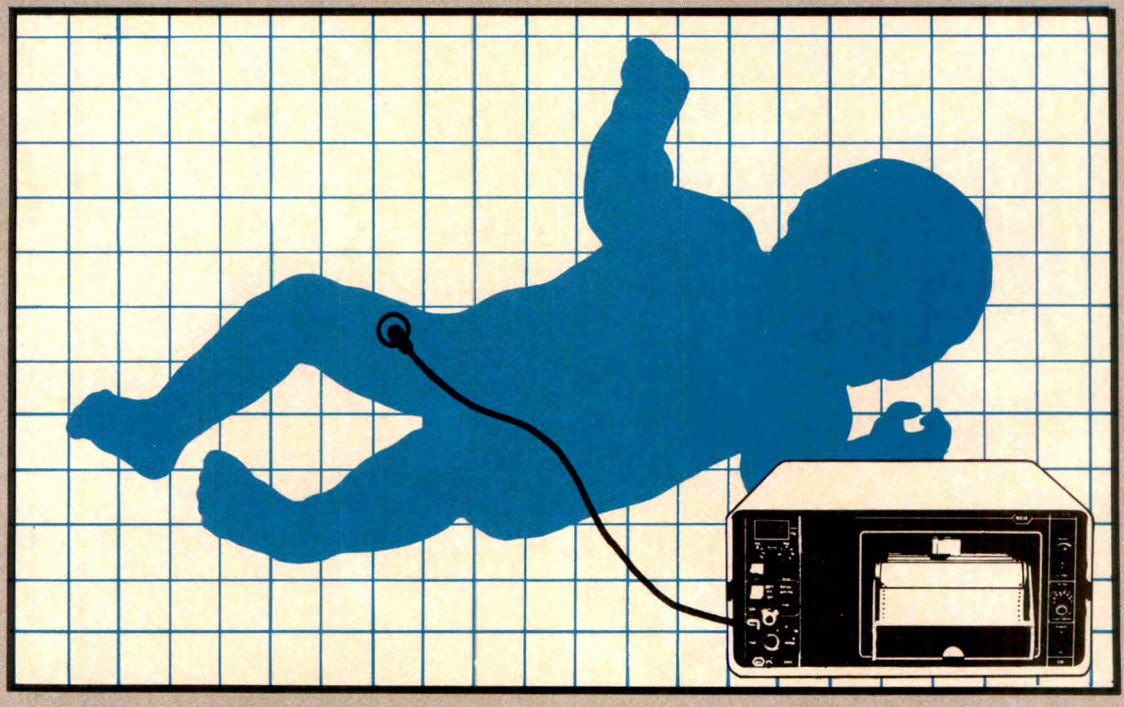
ROCHE Roche

Medical Electronics Inc. is looking for trouble

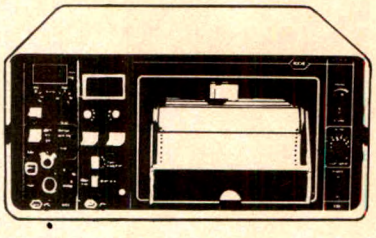
For instance, we looked long and hard at the problem of neonate pH measurement and found the old ways too difficult, time consuming, incomplete and expensive... And we changed it.



The unique, exclusive Roche **Neonatal** pH Monitor* provides a vast improvement over old methods of pH measurement: intermittent blood withdrawal from in-dwelling catheters with potential for trauma. The new Roche **Neonatal** pH Monitor gives you continuous readings through a patented, tiny electrode that attaches comfortably to the skin.

Measurements are recorded on a continuous-run Z-fold chart and low-high alarms can be pre-set to alert the staff to changes in pH. Thus, the new Roche **Neonatal** pH Monitor frees staff from time-consuming and expensive blood sampling.

*Tissue pH or muscle surface pH monitoring.



Note: Not available for fetal monitoring
Sufficient clinical data do not presently exist to warrant use in fetal monitoring at this time...but Roche is working on it.

At last... neonate pH monitoring has a high degree of safety, is automatic and continuous

Announcing the Roche **Neonatal** pH Monitor, the first and only electronic pH monitor: can eliminate the in-dwelling catheter, reduces blood sampling, gives instant and continuous pH measurements and automatically alerts the staff to changes in pH.

Good news if you now own the Roche Model 5302 po_2 Monitor

If you are currently using the Roche Model 5302 $p0_2$ Monitor, it can be adapted easily to add the new Roche pH **Neonatal** Monitor and **increase your capability for automatic, continuous non-invasive monitoring.**

ORTHO ANNOUNCES:
A toll-free, continuing medical education service available 24 hours a day, 7 days a week... see your Ortho Representative for Program Guide, or call toll-free 800-633-4560.*

*Alabama – 800-292-6688; Birmingham – 251-5209.

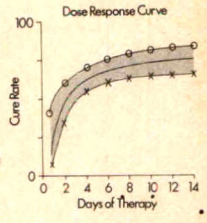
SOUTHERN MEDICAL ASSOCIATION DIAL access

high cure rates in only 7 days

all.

One applicatorful of MONISTAT 7 Vaginal Cream, every night for only 7 nights, produces significantly high cure rates in pregnant† and non-pregnant patients, patients on antibiotics or hormonal therapy, and those treated with other medications. After a single course of therapy, cured patients remained symptom-free with negative cultures throughout the menstrual cycle.

prompt symptomatic relief



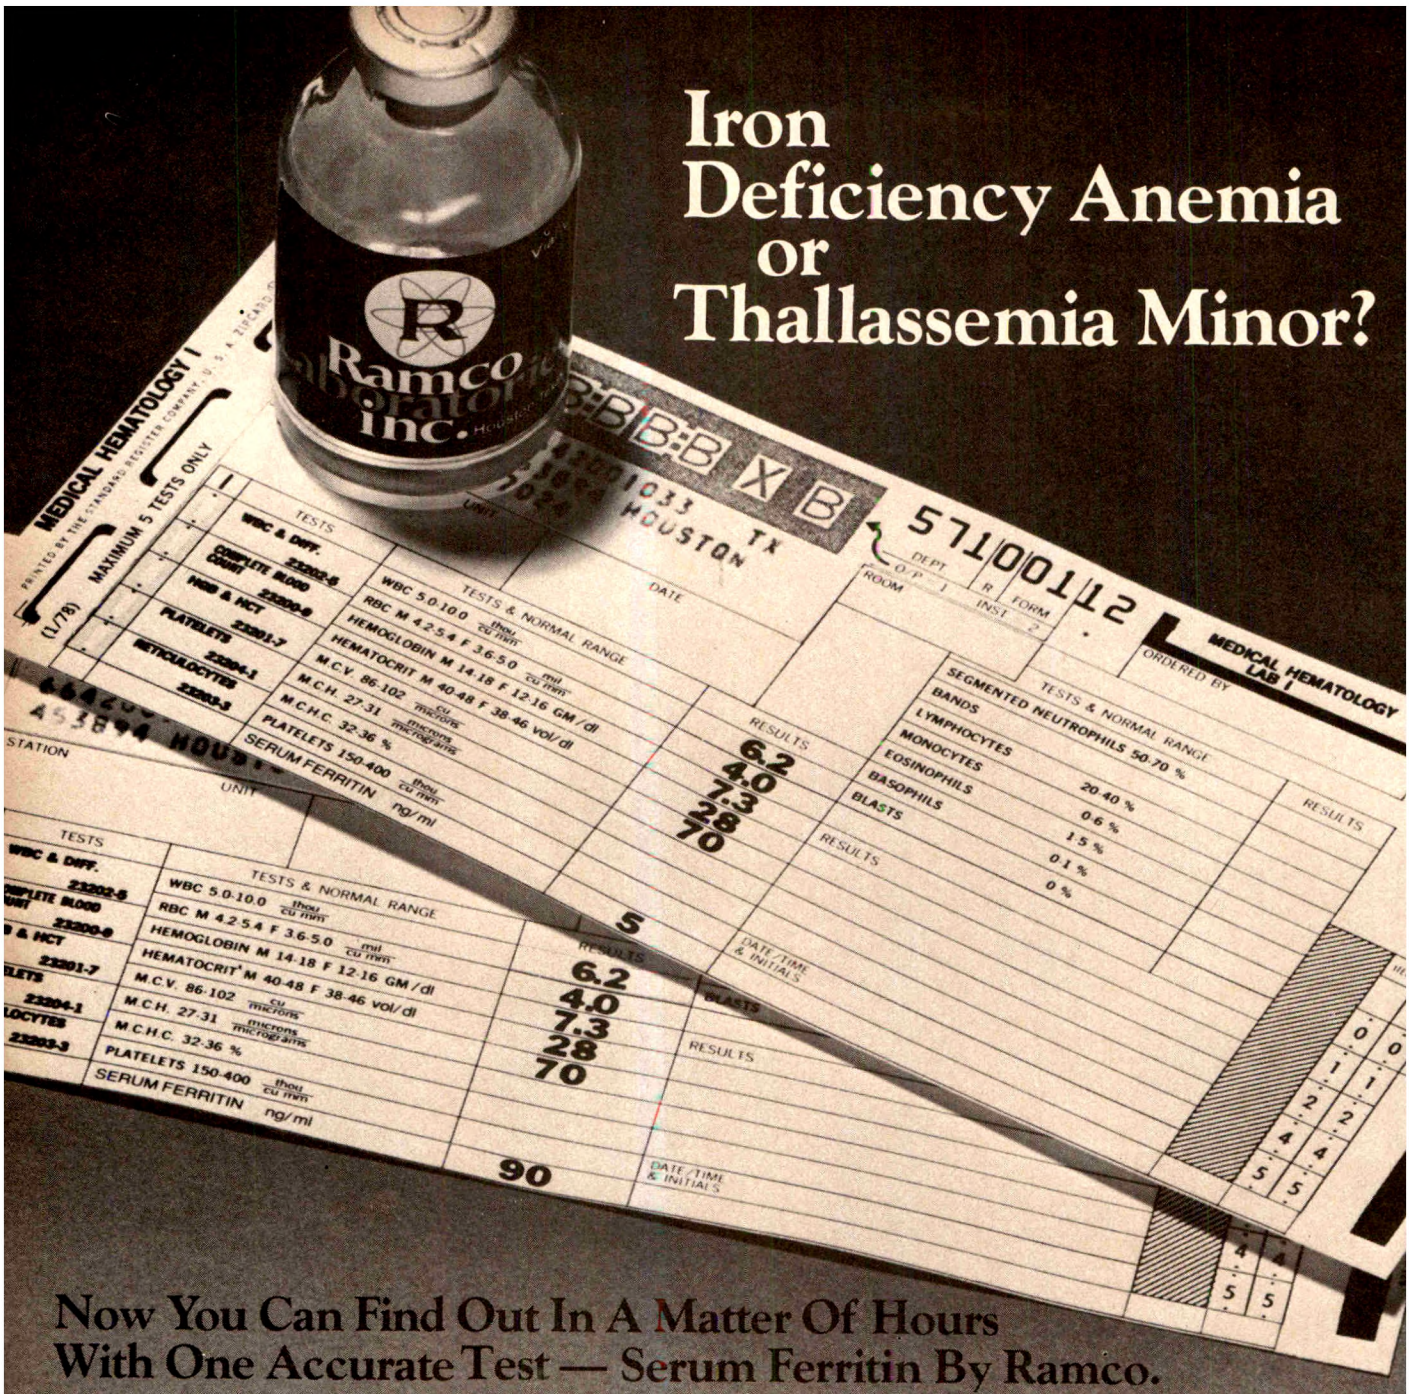
MONISTAT 7 Vaginal Cream contacts rapidly and intimately with infected tissues for prompt relief of symptoms of vulvovaginal candidiasis.

patient acceptance

The shorter, simpler course of therapy is convenient, easy to follow, easy to use, easy to comply with, and well-accepted by many women.

†MONISTAT 7 Vaginal Cream may be used in second and third trimester patients. However, in first trimester patients, it should only be used when the physician considers it essential to the patient's welfare. See Precautions in Prescribing Information.

Description MONISTAT 7 Vaginal Cream (miconazole nitrate 2%) is a water-miscible, white cream containing as the active ingredient, 2% miconazole nitrate, 1-[2, 4-dichloro-β-(2, 4-dichlorobenzyloxy) phenethyl] imidazole nitrate.
Actions MONISTAT 7 Vaginal Cream exhibits fungicidal activity *in vitro* against species of the genus *Candida*. The pharmacologic mode of action is unknown.
Indications MONISTAT 7 Vaginal Cream is indicated for the local treatment of vulvovaginal candidiasis (moniliasis). As MONISTAT 7 Vaginal Cream is effective only for candidal vulvovaginitis, the diagnosis should be confirmed by KOH smears and/or cultures. Other pathogens commonly associated with vulvovaginitis *(Trichomonas* and *Haemophilus vaginalis)* should be ruled out by appropriate laboratory methods.
MONISTAT 7 is effective in both pregnant and non-pregnant women, as well as in women taking oral contraceptives. (See **Precautions**.)
Contraindications Patients known to be hypersensitive to this drug.
Precautions General: Discontinue drug if sensitization or irritation is reported during use. Laboratory Tests: If there is a lack of response to MONISTAT 7, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens.
Pregnancy: Since MONISTAT is absorbed in small amounts from the human vagina, it should be used in the first trimester of pregnancy only when the physician considers it essential to the welfare of the patient. Clinical studies, during which MONISTAT was used for 14 days, included 209 pregnant patients. Follow-up reports now available in 117 of these patients reveal no adverse effects or complications attributable to MONISTAT therapy in infants born to these women.
Adverse reactions During clinical studies with MONISTAT for a 14-day regimen, 39 of the 528 patients (7.4%) treated with MONISTAT reported complaints during therapy that were possibly drug-related. Most complaints were reported during the first week of therapy. Vulvovaginal burning, itching or irritation occurred in 6.6%, while other complaints such as vaginal burning, pelvic cramps, hives, skin rash and headache occurred rarely (each less than 0.2% patient incidence). The therapy-related dropout rate was 0.9%.
Clinical Statistical analysis of randomized clinical trials, conducted to determine the shortest effective course of therapy with MONISTAT, demonstrates that a regimen of seven or more days has a cure rate equivalent to the 14-day regimen. The graphic representation of this conclusion plots days of therapy versus cure rates. The solid line represents the mean therapeutic cure rate and the shaded area represents the 95% confidence interval.



Dosage and administration One applicatorful is administered intravaginally once daily at bedtime for seven days. Course of therapy may be repeated after other pathogens have been ruled out by appropriate smears and cultures.
Supplied MONISTAT 7 Vaginal Cream is available in 1.66 oz. (47 g) tubes with ORTHO* Measured-Dose Applicator. MONISTAT Cream (miconazole nitrate 2%) is a development of Ortho Pharmaceutical Corporation and Janssen Pharmaceutica, Belgium.

Iron Deficiency Anemia or Thallassemia Minor?

Now You Can Find Out In A Matter Of Hours With One Accurate Test — Serum Ferritin By Ramco.

Serum ferritin will accurately separate the two — as iron deficient patients have values of less than 30 ng/ml, while patients anemic for other reasons have values in excess of 50 ng/ml.

Patients with both iron deficiency and thallassemia minor may have microcytosis as shown by a low MCV. However, in iron deficiency anemia, iron stores are decreased and in thallassemia minor, iron stores are normal to elevated.

Simple iron deficiency anemia can be identified by the FER-IRON procedure since the ferritin content of the serum is reduced *only as a result of iron depletion*.

ASK your lab about RAMCO's FER-IRON for the determination of serum ferritin. For more detailed information on the clinical applications of serum ferritin:

GYNECOLOGY

Studies on the cytodynamics of human endometrial regeneration

III. In vitro short-term incubation historadioautography

ALEX FERENCZY, M.D.
GRACIA BERTRAND, B.Sc.
MORRIS M. GELFAND, M.D., F.R.S.C.(C.)
Montreal, Quebec, Canada

The proliferation kinetics of endometrial regeneration were assessed by tracing nucleoprotein precursor, radiothymidine. Increased isotope uptake occurred by cycle day 3 and was confined to the gland cells of denuded stratum basale (basal layer) and persistent uterine lining, bordering peripheral areas of denudation. This increase resulted in the formation of flattened surface epithelial cells, which initially were devoid of significant deoxyribonucleic acid synthesis. Such alterations are consistent with changes in cells involved in ameboid migration. Maturation of migrating cells was accompanied by a significant rise in labeling indices and replication at cycle days 3 and 4. By cycle day 5, endometrial repair was complete. The findings indicate that, following physiologic loss of stratum functionale, endometrial healing involves both migration and replication of surface cells, which originate from the gland stumps of the residual basal layer and the persistent surface epithelium adjacent to the periphery of denuded endometrium. (AM. J. OBSTET. GYNECOL. 134:297, 1979.)

RECENT ULTRASTRUCTURAL STUDIES[1, 2] on regenerating human endometrium revealed that the total approximate generation time for re-epithelialization of postmenstrual surface is 48 hours (±12 hours), beginning between cycle days 2 and 3 in a normal four-day menstrual period. The mechanism of recovery of the denuded surface is by a simultaneous and progressive epithelial outgrowth from the mouths of basal glands and by ingrowth from the surface epithelium adjacent to the denuded areas, namely from the isthmic and peritubal ostia or cornual regions. Both the basal glands and surface epithelium of peripheral uterine regions remain intact during the menstrual period.

The subsequent development of interanastomoses between converging epithelial proliferations leads ultimately to complete reconstruction of a new surface epithelium by cycle day 5. The studies revealed, furthermore, that the predominant proliferative activity during endometrial regeneration is confined to the formation of a new surface epithelium and that the stroma remains relatively inactive until surface re-epithelialization is completed. Since endometrial mor-

phologic changes known to be associated with estrogenic stimulation occur only following complete surface re-epithelialization coinciding with the increasing plasma and tissue receptor levels for estradiol-17β, we have suggested that endometrial surface regeneration is likely a local reaction to injury, presumably induced by loss of endometrial mucosa, and is not mediated by the ovarian hormones.[1, 2]

Experimentally induced endometrial regeneration in the rabbit resembles the resurfacing human endometrial cells in reference to the time sequence of events and site of origin.[3] In vivo historadiographic studies using radiothymidine demonstrated an increase in nucleic acid synthesis in all of the endometrial compartments, which are involved in the repair of lost tissue. Increase of isotope uptake above control levels occurs between six and 12 hours after injury and progresses until the second postexcision day. By day 3 after injury,

endometrial regeneration is completed coincident with a return of labeling index to baseline levels. A rising labeling index in regenerating endometrium is correlated with a gradual increase in both the mitotic activity and areas being repaired. The increase in deoxyribonucleic acid (DNA) synthesis in the resurfacing cells and cells immediately adjacent to them precedes this increase in the stromal fibroblasts by about 18 hours, indicating that the newly formed surface lining derives from the persistent surface epithelium bordering the denuded areas rather than from stromal fibroblasts.

In this article we report the results obtained by in vitro short-term quantitative historadioautography using tritiated thymidine (^{3}H-labeled thymidine) in human endometrium during the menstrual and postmenstrual periods. We were particularly interested in study of the mechanisms, time sequences, and zonal characteristics of endometrial repair and the relationship of nucleic acid synthesis to endometrial cellular compartments involved in postmenstrual endometrial regeneration.

Material and methods

We studied a total of 21 uteri obtained from normally menstruating* women (aged 27 to 42 years) on cycle days 1 and 2 (six uteri); 3 and 4 (six uteri); and 5 to 7 (nine uteri). The selection of patients, data of recovery of specimens, and processing of specimens are described in detail in a previous communication on the scanning electron microscopic aspects of endometrial regeneration.[1] The uteri were opened along the lateral borders under a tissue culture hood within 5 minutes of obtaining them in the operating room. Using sterile instruments and under the guidance of a dissecting microscope, samples were taken from the body, fundus, peritubal ostia, and isthmus (lower uterine segment) regions. Blocks of endometrium measuring 1 by 1 by 0.2 cm. were excised along with a thin layer of subjacent myometrium and placed in a pool of oxygenated sterile Earle balanced salt solution (BBS)† at pH 7.0 at room temperature. Each block of endometrium was pinned on dental plates and minced into 1 sq. mm. tissue fragments, always preserving proper orientation and the whole thickness of the endometrium from the myometrium to the surface. The explants were collected on lens paper, moistened with a drop of Earle BBS, and placed into Petri dishes containing 5 ml. of Trowell T8.† No radioisotope was added to the control dishes containing medium, whereas those dishes for the experiment received 10 μCi per milliliter of methyl–^{3}H-labeled thymidine (specific activity, 47,000 to 50,000 μCi per millimole).* The Petri dishes containing both the test and control tissues were placed in a plastic box sealed with tape, and a gas mixture of 5 per cent CO_2 and 95 per cent oxygen was passed through a pinhole made in the cover of the box. Both the control and test tissues were incubated at 37° C. for one hour. Following incubation, the explants were washed three times in Earle BBS, fixed in Bouin's solution, dehydrated, and embedded in paraffin. Sections cut at 2.5 μ were prestained with hematoxylin and dipped into liquefied nuclear emulsion Kodak NTB2. The radioautographs were exposed for four days, developed in Kodak D-170 for six minutes, and fixed in Kodak Rapid Fixer.

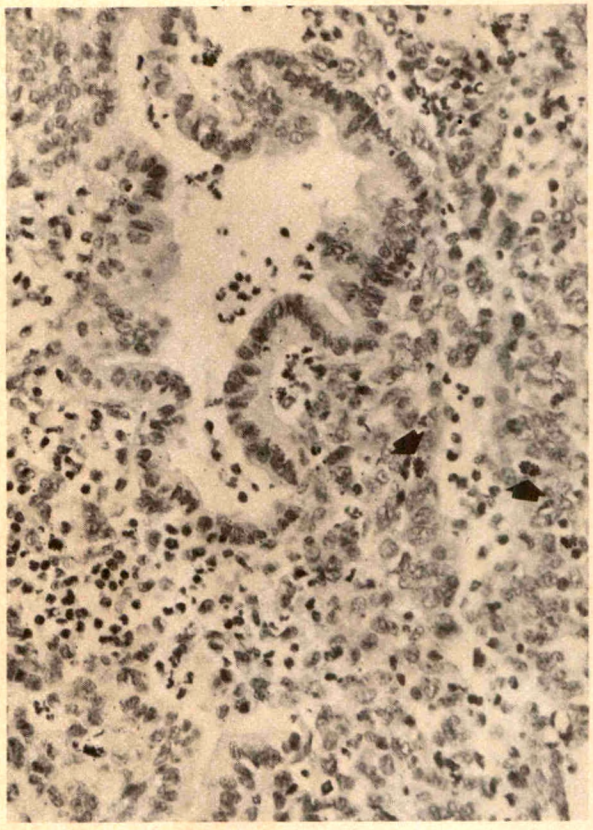

Fig. 2. Radioautograph of glands and predecidua from the lower stratum functionale endometrium from cycle days 1 and 2. Note degenerative features and inconspicuous labeling of predecidual cells (arrows). (Hematoxylin and eosin. Original magnification ×250.)

Interpretation of the radioautographs. Because tritiated thymidine may not label the whole thickness of the tissue fragments, our counts were restricted to the outer third, near the edges of the sections. In this area, grain counts and labeling indices were reproducible.

*The term "menstruation" in this article refers strickly to bleeding from secretory progestational endometrium in association with at least six previous regular ovulatory cycles.

†Gibco.

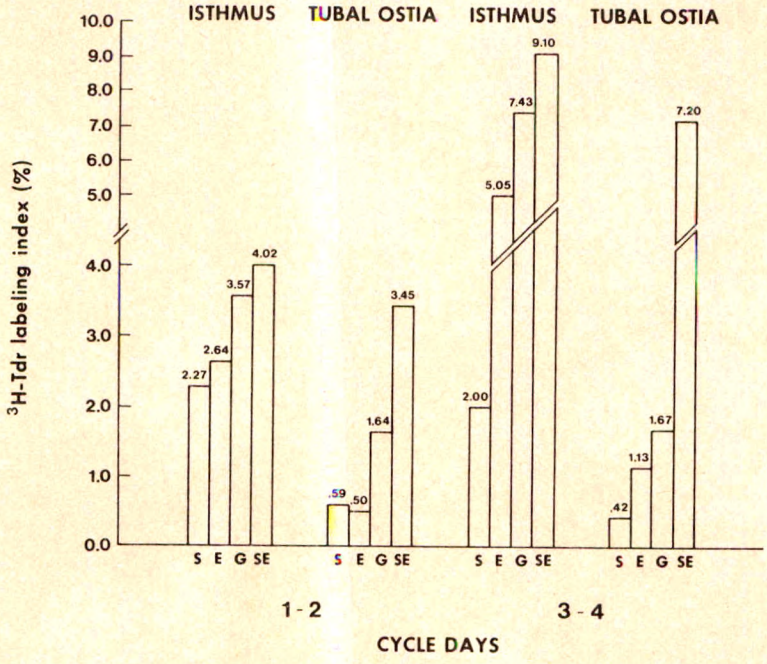

Fig. 3. Zonal and cellular distribution of mean intensity of tritiated thymidine labeling of isthmic and peritubal ostia endometria bordering menstrual endometrium. Note sharp increase in LI on cycle days 3 and 4 coinciding with endometrial regeneration. See Fig. 1 for abbreviations.

Only cells with five or more grains over the nucleus were considered labeled and the percentages of labeled cells were determined by consecutively counting 1,000 to 3,000 cells over: (1) the stratum functionale including the surface epithelium, the glandular epithelium, stromal fibroblasts, and endothelial cells and (2) the basal layer including the regenerating surface epithelium, stromal fibroblasts, and endothelial cells. The labeling index (LI) was then calculated by the following formula:

$$\text{LI (\%)} = \frac{\text{Number of labeled cells} \times 100}{\text{Unlabeled cells}}$$

Because of the limited number of specimens studied and to achieve statistical significance, each count, expressed as a percentage in Figs. 1 and 3 and Tables I and II, represents pooled data from equal areas of three endometria obtained on each cycle day.

Results

There were no appreciable quantitative differences in isotope uptake between the fundus and body regions of the endometrial cavity and thus the findings obtained in these regions will be described as one. The pattern of DNA synthesis was uniform in the various endometrial segments and cellular compartments with a variation of less than ±1.5 per cent.

First- and second-day menstrual endometrium. The distribution of labeling intensity by tritiated thymidine (expressed as a mean) in various tissue components of the endometrium is shown in Fig. 1. In accordance with the massive degeneration of secretory endometrial tissue of the stratum functionale of the fundal and body regions, isotope uptake was negligible (Fig. 2) in both the glandular and surface epithelia with mean LI's of 0.10 and 0.21 per cent, respectively. The predecidual and vascular endothelial cells of menstruating stroma demonstrated similar low levels, 0.24 and 0.16 per cent, respectively. The LI in the basal layer was even lower, with the exception of the glandular apparatus, 0.13 per cent (Fig. 1).

The pattern of DNA synthesis in areas that were not involved in the menstrual breakdown, such as the peripheral isthmic region, remained essentially unchanged (Fig. 3) from that observed during the postmenstrual proliferative or secretory phase of the menstrual cycle (mean LI of isthmus is constant during the menstrual cycle: surface epithelium, 4.7 per cent; glandular epithelium, 3.3 per cent; stromal fibroblasts, 2.2 per cent; and vascular endothelium, 2.0 per cent.[4] On the other hand, in the region of the peritubal ostia, only the surface and glandular epithelia demonstrated an LI unchanged from that observed during the proliferative phase (mean LI's of surface and glandular epithelia of tubal ostia during the proliferative phase are 3.9 and 1.5 per cent, respectively).[4] The adjacent and subjacent stromal tissue, including the predecidua and capillary endothelium, demonstrated degenerative

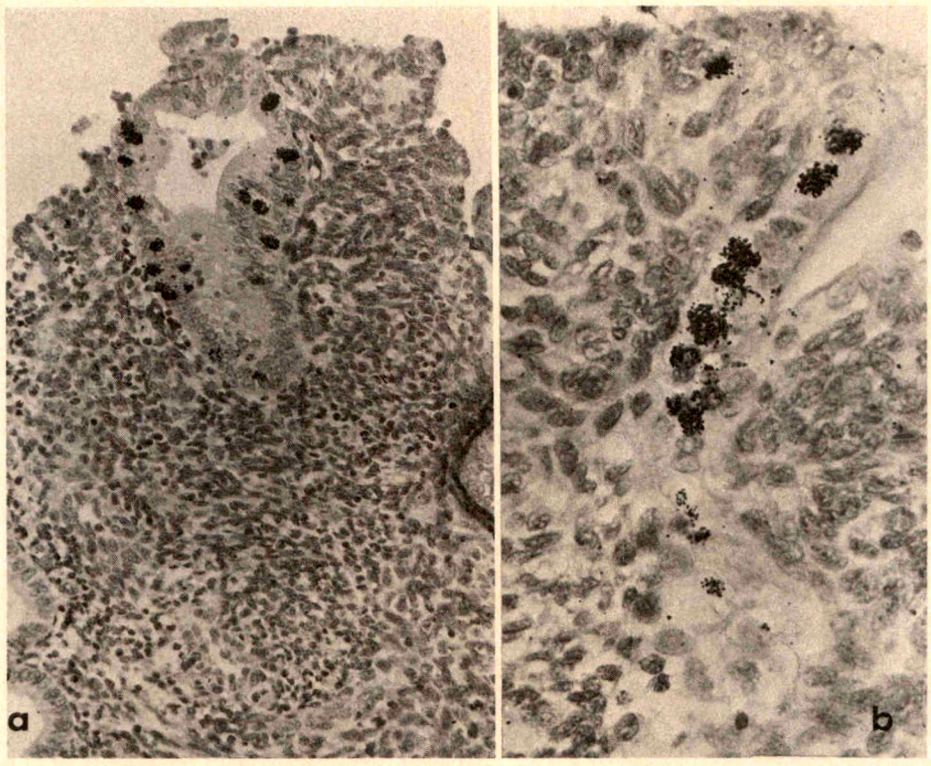

Fig. 4. *(a)* Radioautograph of denuded basal glands of endometrium from cycle days 3 and 4. Note heavy labeling is confined to gland lining cells. (Hematoxylin and eosin. Original magnification, ×250.) *(b)* Higher magnification illustrating concentration of labeled cells at the basal gland neck region. (Hematoxylin and eosin. ×400.)

changes with mean LI values very similar to those in the fundal regions (Fig. 3).

Third- and fourth-day menstrual endometrium. During this period, regeneration rather than degeneration prevailed. In areas where denudation had occurred following desquamation of the degenerated stratum functionale, a dramatic increase in LI (6.08 per cent) was observed in the basal glands (Fig. 1). Isotope uptake was concentrated near the free stumps of glands of the residual basal layer (Fig. 4). In areas of surface re-epithelialization, the LI increased in favor of the newly formed surface epithelial cells, with a mean LI of 5.15 per cent, whereas it decreased sharply in the subjacent gland cells of the zona basale (Figs. 1 and 5). The distribution of radioisotope in the resurfacing and apparently expanding surface epithelial cells followed the same pattern both in the fundus-body and the isthmic and peritubal ostia regions, and was correlated with changes in cell morphology. While tritiated thymidine uptake was neglibible (mean LI, 0.2 per cent) in the earliest, spindle-shaped resurfacing cells, DNA syntheis had increased sharply in the cuboid and columnar cell variety (Fig. 6), with mean LI's of 7.0 and 7.5 per cent, respectively (Table I).

Coinciding with epithelial resurfacing, the underlying stromal fibroblasts and capillary endothelial cells demonstrated approximate fourfold (0.41 per cent) and tenfold (1.44 per cent) increases in DNA syntheis, respectively, as compared to areas of denudation (Fig. 1). Isotope incorporation also increased significantly in areas bordering zones of degeneration, including the isthmic and peritubal ostia regions. However, when values are compared with those of cycle days 1 and 2, the mean LI's of 7.43 per cent for the glandular epithelium and 9.10 per cent for the surface epithelum of the isthmus represent only about twofold increases (Fig. 3) as compared to the more than sixfold increase for the surface epithelial system of the regenerating basal layer of the uterine fundus-body (Fig. 1).

With regard to nuclear DNA synthesis in the peritubal ostia region, only the persistent surface epithelium showed a twofold increase in LI, whereas the glandular epithelium remained unchanged from previous days of the menstrual period (Fig. 3). The stromal fibroblasts in this region as well as in the isthmus demonstrated no significant differences in mean tritiated thymidine uptake when compared to that found in prior regeneration; however, a twofold in-

Fig. 5. Radioautograph of regenerated endometrium on cycle day 4. Resurfacing of denuded basal layer is associated with an increase in labeled surface cells and decrease or absence of isotope uptake in the subjacent basal gland cells. (Hematoxylin and eosin. Magnification ×320.)

crease in LI was observed in the vascular endothelium (Fig. 3).

Endometrium of cycle days 5 to 7. The relative LI's of various layers of the endometrial mucosa and cellular components are listed in Table II. Once epithelial resurfacing has been completed by cycle day 5, a dramatic increase in nuclear DNA synthesis is observed in all the cellular components of the young stratum functionale, with maximum values in the glandular epithelium. There were no significant variations in LI between the body and fundus regions. The sudden increase in LI is accompanied by the appearance of mitotic activity in stromal and endothelial cells as well as in surface and gland lining cells. On the other hand, the elevated LI observed during cycle days 3 and 4 in epithelial lining of the isthmic endometrium and peritubal ostia surface bordering denuded areas, declined sharply (Table II) and almost returned to the level found on first menstrual day (Fig. 1). On cycle days 8 to 10, a further increase in LI and mitotic activity of the stratum functionale endometrium of the body-fundus is observed.[4]

Comment

The results confirm earlier observations[1, 2] that endometrial regeneration begins by cycle day 3 following menstrual tissue necrosis, results in the formation of new surface epithelial cells, which are the hallmarks of endometrial repair, and is completed by cycle day 5. The finding of a significant regenerative response in endometrium during the menstrual period suggests previous endometrial degeneration. Indeed, syntheis of nuclear DNA was near zero levels in the secretory stratum functionale of the endometrium of body and fundus regions during cycle days 1 and 2. The findings are consistent with our previous ultrastructural observations, which have indicated that the stratum functionale, including the glandular, predecidual, and endothelial cells, undergoes irreversible cell injury from prior expulsion during periods of menstruation.[2] The observations are also in harmony with those of Epifanova,[5] according to whom secretory differentiation implies an arrest in cell growth on the one hand and a prelethal state on the other. However, Flowers and Wilborn,[6] after using electron microscopy with ruthenium red stain as an indicator for dead or injured cells, suggested that the secretory spongiosa remains viable during the menstrual period and is converted by autophagocytosis and heterophagocytosis of intra- and extracellular debris into a replicating endometrium. The discrepancies in observations may be attributed to different interpretations of cellular changes occurring during menstruation as well as different techniques used for sampling and studying uterine specimens.

In the present study, DNA syntheis was confined to the basal layer of the body-fundus of the uterus as well as the endometrial mucosa of the isthmus and peritubal ostia, all of which remained intact during menstruation. Significant increase in LI in these regions occurred only following complete denudation of the zona basale by cycle day 3. The sudden and marked rise in labeling intensity of the glandular epithelium, but not of stromal fibroblasts, in areas of denuded basal layer

and its sharp decrease coinciding with the appearance of resurfacing epithelial cells concur with the proposal that the newly formed surface lining derives principally from the persistent glandular epithelium of the basal layer.[1, 2, 7–10] A similar labeling pattern observed in the isthmic and peritubal ostia mucosae bordering the denuded endometrial cavity indicates their contribution to the peripheral repair of lost tissue. This contention is supported by experimental studies in the rabbit in which partial removal of the entire thickness of endometrial mucosa including the basal layer is reconstructed by the peripheral ingrowth of surface epithelial cells originating in the endometrium adjacent to mechanical denudation.[3, 11]

According to the present radiothymidine labeling study and previous ultrastructural observations,[1, 2, 10] postmenstrual endometrial repair involves both cellular migration and replication. The initial response was spreading and migration of new surface epithelial cells from the free stump of basal glands and peripheral wound edges into the denuded area. Migration was observed about six to 12 hours prior to increased DNA synthesis in the surface epithelial cells. This sequence of initial cellular expansion and subsequent cellular replication has also been observed in mechanically denuded rabbit endometrium.[3] Endometrial surface cells on the edge of denudation lacked DNA labeling and mitosis and were flattened with well-equipped, intracytoplasmic, microfilamentous-microtubular systems and pseudopodial projections.[1–3] These alterations have been ascribed to migrating-type cell populations in both in vivo and in vitro conditions.[3, 12, 13] The initial spread of first-produced, first-to-migrate surface lining appears to form an expanding network of cells over denuded area in which DNA synthesis and mitosis subsequently occur. This was evidenced by an increase of LI in surface cells as compared to the underlying basal cells during the third and fourth days of the cycle, which are dominated by wound healing reaction. As in the rabbit endometrial regeneration system, increased nuclear DNA activity and mitoses were correlated with maturation of surface cells from spindle shaped to cuboid and with repopulation of surface areas. DNA-mediated proliferative activity remained unchanged as the cuboid surface cells acquired a cylindrical shape and surface re-epithelialization was completed. Consequently, during the first six to 12 hours of the regenerative period starting from about day 3, spreading and migration appears to be the principal means to rapidly reconstitute endometrial integrity, whereas for the period thereafter, DNA synthesis, cell division, and migration continue simultaneously until a confluent surface layer has been regenerated, on cycle day 5.

Since significant increase of radiothymidine labeling of stromal fibroblasts and vascular endothelium was demonstrated in areas of active regeneration, it is reasonable to assume that these cells also participate in endometrial mucosal remodeling. Ultrastructurally, stromal fibroblasts were shown to be engaged in phagocytosis and presumably digestion of degenerated residual products of extracellular origin, whereas an increased number of organelles, principally free and bound ribosomes, enlarged cytoplasmic substance, and irregular membranes characterized endothelial cells of capillaries.[2, 3] Such endothelial alterations have been described in a variety of experimental injuries and are considered a reflection of regenerating type of endothelium.[12]

In an earlier communication, we have postulated that the new surface epithelium, characterized by negligible mitotic activity, nuclear enlargement, and abundant intracytoplasmic RNA synthesis, proliferates by endomitotic division,[2] On the basis of the present

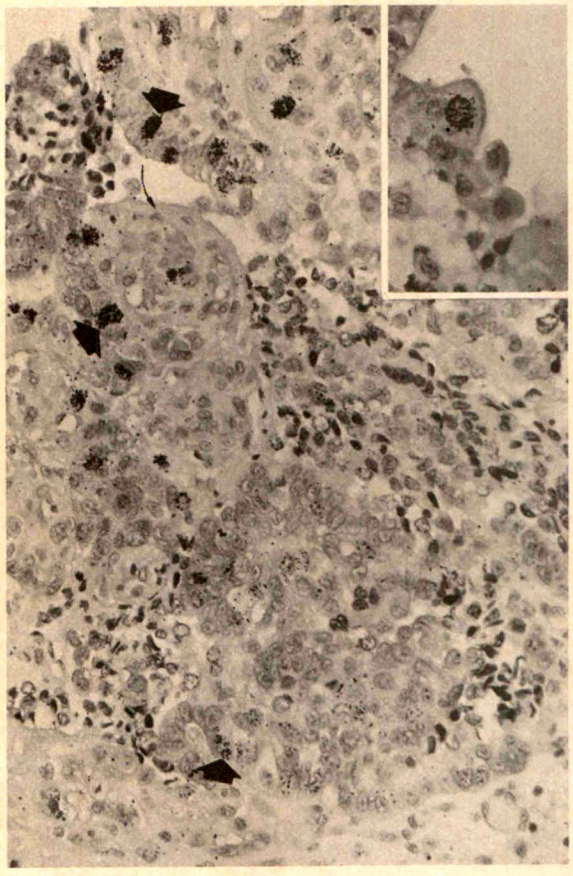

Fig. 6. Radioautograph of labeled surface epithelial cells (large arrows) displaying cuboid and columnar differentiation, on cycle days 3 and 4. Note lack of labeling in flattened variety of surface epithelium (curved arrow). (Hematoxylin and eosin. Magnification ×280.) Inset shows detail of nuclear labeling pattern of a cuboid surface cell. (Hematoxylin and eosin. Magnification ×400.)

study, the relative paucity of mitotic activity despite prompt restoration of postmenstrual endometrial surface may additionally be explained by (1) the distribution of replicating cell populations during periods of regeneration and (2) pattern of wound healing. Assuming that a complete cell cycle lasts about 10 hours, including eight hours for DNA synthesis and one hour for the mitotic phase, one would expect to see at least one cell in mitosis for every 10 cells labeled with radiothymidine. LI's of 6.0 and 1.7 per cent in basal glands in areas of denudation and surface regeneration, respectively, should therefore yield very few mitotic figures. The demonstration of an important migratory component devoid of mitosis during early periods of endometrial regeneration contributes further for the rarity of division figures.

The mechanism of induction of endometrial proliferation during menstruation is unknown. However, the lack of estrogen-related histologic and ultrastructural alterations in postmenstrual regenerating endometrium,[1, 2] together with DNA activity essentially limited to the regenerating epithelial and endothelial cellular systems and with low levels of plasma estradiol during cycle days 1 to 4, suggests that postmenstrual endometrial resurfacing is not influenced by estradiol-17β. This suggestion is supported by our previous observations on experimental endometrial regeneration in the rabbit, in which isotope uptake and ovariectomy-associated morphologic alterations of the regenerative but estrogen-deprived atrophic endometrium were similar to alterations in animals with intact ovaries.[3] On the other hand, the sudden increase in both nuclear DNA synthesis and mitosis in the stromal, vascular, and gland cell components of regenerated human endometrium on cycle days 5 to 7 and their further increase on cycle days 8 to 10[4] are consistent with preovulatory estradiol-17β–stimulated DNA synthesis and tissue growth.

In general, necrotizing injury causes cell death, thereby interrupting cellular integrity and continuity and resulting in proliferation. The observation of proliferation at the injury site as well as some distance from the wound area suggests the possibility of a diffusible substance(s) that would trigger migration and replication-mediated growth. Since endometrial repair is not initiated until complete denudation has occurred, it is also conceivable that repair of lost tissue is a function of temporary loss of inhibitor(s) of tissue growth, such as the tissue-specific, species-nonspecific inhibitor of mitosis, chalone.[14] Stabilization of DNA synthesis as the new surface epithelial cells reach maturation and complete re-epithelialization of the denuded zona basale may suggest proliferation-inhibition mechanism controlling wound healing.

A series of transcervical uterine biopsy specimens were obtained at various stages of the menstrual cycle from a colony of 11 normally cycling female baboons, *Papio anubis* and *Papio cynocephalus*. Morphologically, baboon endometrium appeared to be similar to human endometrium. Alkaline phosphatase activity was maximal throughout the preovulatory phase and during the late postovulatory period. During the preovulatory phase acid phosphatase was not demonstrable but increased after ovulation to reach maximal activity prior to menstruation. While differences exist between human and baboon endometria, the overall morphologic and histochemical changes are similar. In addition, the baboon's endometrium is readily accessible by transcervical uterine biopsy, thus making these animals valuable primate models for study of human reproductive problems.
(AM. J. OBSTET. GYNECOL. 134:305, 1979.)

MANY HISTOCHEMICAL and biochemical studies have shown that fluctuations occur in enzyme activity and carbohydrate content in the human endometrium throughout the menstrual cycle.[1] These endometrial alterations are under the control of the ovarian steroids, estrogen and progesterone, and are reflective of changes in plasma concentration of these two hormones.

In contrast to studies of human endometrium, only a few studies have been conducted on baboon endometrial modulations and none of these has focused on enzymatic distribution or activity throughout the menstrual cycle.[2-4] Because of the baboon's close phylogenic relationship to man, it is being used increasingly as a model in reproductive biology. In addition, the endometrium of the baboon can easily be sampled by transcervical biopsy. Therefore these animals could be valuable models in studies that require frequent sampling of the endometrium. However, prior to the acceptance of the baboon as a valid animal model, a more thorough evaluation of its menstrual cycle in terms of both physiologic and morphologic observations is needed. Thus, in the present study, acid and alkaline phosphatase activities were investigated in baboon endometrium and compared to the well-established fluctuations of those enzymes that occur in human endometrium.

Material and methods

A colony of 11 normally cycling female baboons, *Papio anubis* and *Papio cynocephalus*, was used for this research. Daily records of sex skin turgescence and menses were kept for each of the animals. Both of these parameters enabled determination of the day of the menstrual cycle. An average menstrual cycle in our baboons was 32 days. The day of ovulation was determined[4] (day 0) and the cycle day identified as being before (−) or after (+) ovulation.

Endometrial tissue was obtained by transcervical uterine biopsy using a Novak curette after anesthetiz-

ing the animals with an intramuscular injection of ketamine HCl. Eighteen endometrial biopsy specimens (six preovulatory, 10 postovulatory, and two during menses) were obtained for light microscopic and histochemical evaluation.

One half of the endometrial sample was fixed in neutral buffered formalin (10 per cent for 24 hours at 4° C., embedded in paraffin, sectioned at 6 μm, and stained with hematoxylin and eosin. The other half of the endometrial sample was rapidly frozen on dry ice and sectioned at 10 μm in a cryostat at −20° C. These sections were incubated for the demonstration of either acid or alkaline phosphatase by two different techniques. One was a modification of the original Gomori metal salt procedure[5] while the other involved an azo dye technique.[6] In all controls for the alkaline phosphatase reaction the substrate was omitted. For acid phosphatase, the control consisted of the addition of 0.01M sodium fluoride to the media. All sections were incubated in Coplin jars for 30 minutes at 37° C.

Results

Histology. The histologic changes that occurred in baboon endometrium during the menstrual cycle correlated with the changes that have been described in human endometrium,[7] thus confirming previous reports by MacLennan and Wynn[2] and Kraemer and colleagues.[4] In addition, granulated endometrial stromal cells were observed infrequently in the last half of the postovulatory period in the baboon. These cells contained small eosinophilic granules within their cytoplasm and resembled the granulated endometrial stromal cell that has been described in human endometrium[8] and macaque endometrium.[9]

Histochemistry. The results obtained with either the modified Gomori metal salt method or the azo dye technique correlated for all phases of the menstrual cycle. Controls for acid and alkaline phosphatase activity were negative.

Alkaline phosphatase. Maximal alkaline phosphatase activity, limited to the endometrial glands, is demonstrable throughout the preovulatory phase (days −14 to −1). The activity of the enzyme within the glands, exhibited as a dark precipitate, is evenly distributed throughout the cytoplasm (Fig. 1, *A*).

During the early postovulatory phase (days +1 to +7), overall alkaline phosphatase activity decreases. However, activity within the supranuclear cytoplasm remains high (Fig. 1, *B*), while the perinuclear and subnuclear areas demonstrate a marked decrease in activity. The stromal cells fail to exhibit alkaline phosphatase activity.

During the last half of the postovulatory phase (days +8 to +16), alkaline phosphatase achieves maximal levels comparable to those of the preovulatory period (Fig. 1, *C*). Heavy precipitation is observed in all areas of the glandular cells and the lumen is partially occluded. However, stromal cell activity is still negligible.

Alkaline phosphatase activity on the first day of menses shows a drastic decline, generally being the lowest seen during the menstrual cycle. Enzyme activity is present only as trace amounts within the apices of the endometrial glandular cells (Fig. 1, *D*). The stromal cells show no alkaline phosphatase activity.

Acid phosphatase. Acid phosphatase activity was not demonstrable throughout the preovulatory phase (days −14 to −1) (Fig. 2, *A*). This observation was true for both the stroma and the endometrial glands.

During the early postovulatory phase (days +1 to +7) acid phosphatase activity began to increase within the endometrial glandular cells. This activity, displayed as a dark precipitate, is most noticeable within the apices of the glandular cells (Fig. 2, *B*). However, trace amounts of granular reaction product are distributed diffusely throughout the cytoplasm of the glandular cells. Certain glandular cells show clumps of precipitate located within the basal region of the cells. The stroma, except for a few scattered granules, is negative for acid phosphatase reaction.

In the late postovulatory phase (days +8 to +16), acid phosphatase activity increases to its highest level within the glands (Fig. 2, *C*). Both the lumen and supranuclear cytoplasm are completely filled with reaction product. Within the subnuclear cytoplasm, the enzyme's activity is not as great, while activity in the stromal cells remains unchanged from that of the early postovulatory phase.

Striking changes are observed on the first day of menses. Acid phosphatase activity is diminished and is primarily concentrated in either the subnuclear or supranuclear cytoplasm (Fig. 2, *D*). The stroma, which until now has been essentially negative for acid phosphatase, contains numerous, evenly dispersed, fine granules.

Comment

In the present study, the acid phosphatase activity of baboon endometrium parallels the activity observed in women.[10] Acid phosphatase could not be demonstrated during the preovulatory phase and first appeared during the early postovulatory period. Enzyme activity continued to increase during the postovulatory phase and reached a peak prior to menstruation. During menstruation, acid phosphatase activity could be dem-

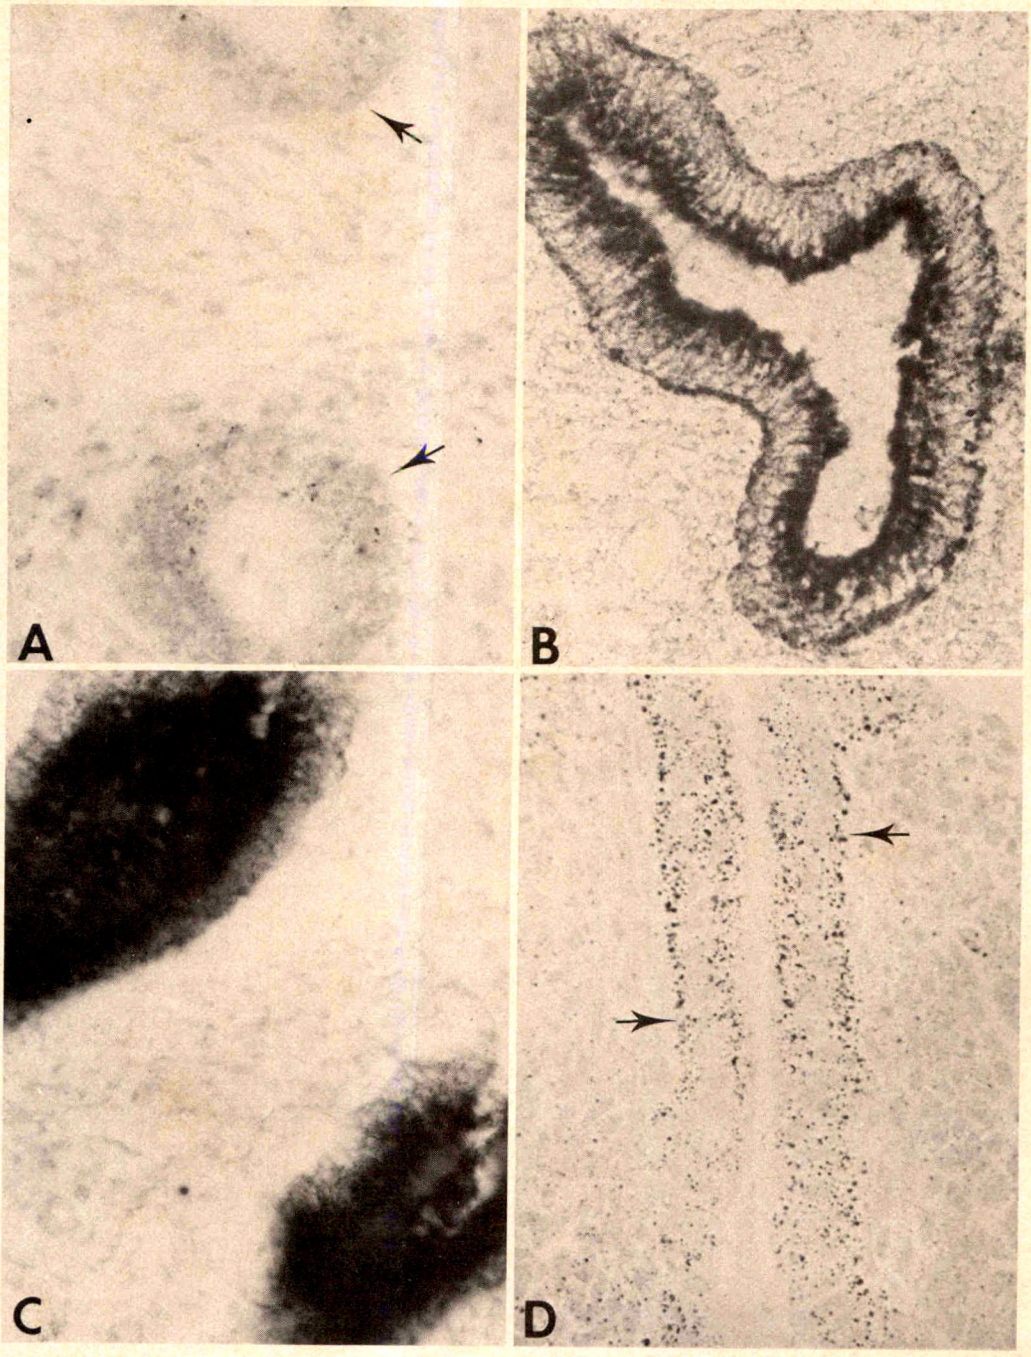

Fig. 2. *(A)* Preovulatory endometrium (day −3) reacted for acid phosphatase. The stroma and portions of two endometrial glands (arrows) are shown. No activity is observed in either element. *(B)* Acid phosphatase activity of early postovulatory endometrium (day +3). The heaviest activity is located within the apices of the glandular cells; however, some precipitate is dispersed throughout the cytoplasm. *(C)* Acid phosphatase activity of late postovulatory endometrium (day +15). Acid phosphatase activity in the glandular cells increases during the late secretory period. Extensive activity is observed within the supranuclear cytoplasm. *(D)* Acid phosphatase activity of endometrium on the first day of menses. Within the glandular epithelium (arrows), acid phosphatase activity is evenly distributed between the apical and basal regions of the glandular cells. Acid phosphatase activity is also demonstrable for the first time within the stromal cells. (Original magnifications ×400.)

onstrated within the baboon stromal cells, as it was in human studies.[11]

Alkaline phosphatase in the baboon displayed maximum activity throughout the preovulatory phase and again in the late postovulatory phase. In contrast, the enzyme's activity decreased immediately after ovulation. In women, alkaline phosphatase reaches a peak prior to ovulation and then begins to decline during the postovulatory phase.[12] These enzyme fluctuations in women are thought to be under hormonal control; presumably estrogen stimulates alkaline phosphatase activity while progesterone is an inhibitor. In the present study, the decrease in alkaline phosphatase activity after ovulation correlated with a decline in plasma estrogen levels and increasing progesterone levels.[13, 14] The increased alkaline phosphatase activity observed during the late postovulatory phase occurs at a time when the estrogen levels are similar to those detected in the preovulatory phase and when progesterone is again approaching preovulatory levels. Thus it appears that baboon endometrial alkaline phosphatase is under control of ovarian hormones in a manner identical to that in women.

In summary this study supports the conclusions by MacLennan and Wynn[2] that the morphologic features of baboon endometrium are similar to those of human endometrium. In addition, our histochemical observations are similar to other findings in human endometrium. Such findings suggest that the baboon would be a satisfactory primate model for the study of human reproductive problems. In addition, the accessibility of the baboon's endometrium makes these animals particularly useful in studies that require frequent sampling of endometrium. Because of the similarity of the baboon and human menstrual cycles and the accessibility of the baboon's endometrium, it could be extremely valuable in studies that may present too great a risk if conducted in women.

We thank Drs. Robert Dyer, John McCormack, and Richard Peppler for their review of the manuscript. In addition, we would like to express our gratitude to Ms. Sandra Weaver and Mr. Garbis Kerimian for excellent secretarial and photographic assistance, respectively.

A syndrome characterized by recurrent symptomatic functional ovarian cysts in young women

SERGIO C. STONE, M.D.
WILLIAM J. SWARTZ, PH.D.
New Orleans, Louisiana

A syndrome characterized by the persistent recurrence of symptomatic functional ovarian cysts, elevated plasma estradiol levels, and infertility in four young patients is described. Two of the patients experienced recurring ovarian cysts following total abdominal hysterectomy and bilateral salpingo-oophorectomy. Pathologic findings confirmed the presence of ovarian tissue in all cysts. Recurrent cysts formation is attributed to either an increased production of gonadotropins or a hypersensitive response to normal gonadotropins. The development of recurrent cysts following bilateral oophorectomy indicates that some ovarian or "ovarian-like" tissue is present within the pelvic cavity, anatomically unrelated to the normally positioned ovaries. This extraovarian tissue may become sensitive to circulating gonadotropin levels in the absence of normal ovarian tissue. The source of this extraovarian tissue is discussed from an embryologic standpoint. (AM. J. OBSTET. GYNECOL. 134:310, 1979.)

BENIGN OVARIAN CYSTS are commonly classified as either nonneoplastic or epithelial.[1] Nonneoplastic cysts can be functional, that is, they respond to circulating estrogens and gonadotropins.[1, 2] Functional ovarian cysts of this type may develop as a result of a hypothalamic-pituitary dysfunction with an abnormal process of cyclical follicular maturation and corpus luteum formation.[1]

Follicle cysts, the most common type of functional cyst, are usually small and asymptomatic. They generally undergo spontaneous resorption and, thus, for the most part remain undiagnosed. On occasion, however, such cysts become large enough to produce discomfort or pain. They may become hemorrhagic and torsion of the pedicle may occur.[1] Such functional cysts are capable of producing estrogen[3] and are the most common cause of pseudoprecocious puberty in girls.[1, 4] The appearance of functional follicular cysts during the normal reproductive life of women may cause irregular menstrual cycles.[1, 2]

Treatment of young women is expectant and ovarian suppression is advocated to accelerate the process of resorption.[1, 2] Surgical intervention is rarely indicated since such cysts disappear spontaneously.[2]

The present report details the persistent recurrence of symptomatic functional cysts and accompanying elevations of plasma estradiol levels in four young patients. Two of the patients experienced recurring cysts following total abdominal hysterectomy and bilateral salpingo-oophorectomy. The others developed recurrent ovarian cysts upon interruption of ovarian suppression. These symptoms were accompanied by infertility. This study offers explanations of this syndrome and suggests that such condition may not be as rare as generally indicated.

Case reports

Case 1. V. B., a 28-year-old, white woman, gravida 0, had a long history of primary infertility, irregular cycles, and anovulation. Prior to consultation in our Section of Reproduction, this patient experienced recurrent symptomatic ovarian cysts necessitating exploratory laparotomy on two occasions. On each occasion large, simple follicular cysts were removed. During the last surgical procedure, bilateral ovarian wedge resection and cauterization of pelvic endometriosis were also performed. She was placed on a regimen of oral contraceptive therapy for several months.

Pain and a right lower quadrant mass recurred a few weeks after discontinuation of the ovarian suppression, at which time she was referred to us. A right pelvic mass adjacent to the uterus was easily palpable and the plasma estradiol level was 102 pg/ml. Suppression of the mass with oral contraceptives (Norlestrin, 2.5 mg) was initiated. Within three weeks the right adnexal mass had disappeared and the plasma estradiol level had decreased to 11 pg/ml. Oral contraceptive suppression was stopped.

Three weeks later the patient returned, again complaining of right lower quadrant pain. A right pelvic mass was palpable and the plasma estradiol level had risen to 149 pg/ml. A regimen of long-term ovarian suppression was started and has continued for the past six months. This patient strongly desires to become pregnant.

Case 2. S. Z., a 21-year-old, white woman, gravida 0, had a long history of recurrent ovarian cysts beginning at age 10. Exploratory laparotomy at that time revealed a 10 cm left ovary, twisted and infarcted. The right ovary was also enlarged and cystic. A left oophorectomy and partial resection of the right ovary were performed. Pathologic findings revealed both ovaries to contain serous, hemorrhagic follicular cysts with stromal hemorrhage and capsular fibrosis.

The patient began using oral contraceptives at 14½ years of age. Later, the patient desired pregnancy and oral contraceptives were discontinued. One month later, she complained of right lower quadrant abdominal pain. Pelvic examination revealed a 6 to 8 cm right adnexal mass.

Oral contraceptive therapy was reinitiated and two weeks later she was asymptomatic and the cystic mass had decreased in size. Oral contraceptives were administered for only one cycle. One month later the patient again complained of right lower quadrant abdominal pain associated with nausea and dizziness. Plasma estradiol at this time was 581 pg/ml. Oral contraceptives were again begun and the patient displayed subjective improvement after 5 days of hormonal suppression, at which time pelvic examination revealed a smaller right ovary and a plasma estradiol level of 21 pg/ml. The patient remained asymptomatic for one year with normal pelvic examinations. Ovarian suppression was then stopped.

One month later she complained of abdominal pain and a pelvic examination revealed the right ovary to be 5 cm in diameter. She was observed without therapy for 2 weeks, remaining symptomatic. Oral contraceptives were begun again and the pelvic examination became normal. The patient, presently on a regimen of long-term oral contraceptive therapy, remains asymptomatic with low plasma estrogen levels. However, she still desires pregnancy.

Case 3. P. M. M., a 26-year-old, white woman, gravida 1, para 1, had a normal delivery in 1971. Following delivery the patient used oral contraceptive therapy intermittently for one year. One month after cessation of oral contraceptives the patient developed heavy vaginal bleeding and a large right ovarian cyst. This was to mark the beginning of several years of almost constant symptomatology as a result of frequent recurrent cysts.

She underwent laparoscopy followed by laparotomy and removal of the right ovarian cyst. A bilateral wedge resection was also performed with the clinical impression of polycystic ovarian syndrome that was not confirmed by pathologic examination.

One month following operation, a cystic, tender adnexal mass was palpated. For the next year and a half, she had numerous episodes of low abdominal pain, irregular vaginal bleeding, and palpable pelvic masses, treated intermittently with oral contraceptives and estrogen therapy. She was finally hospitalized for pulmonary embolism, at which time estrogen therapy was stopped.

Six months after estrogen treatment was stopped, she developed severe left lower quadrant pain and a large, left, tender, cystic mass was palpated. Exploratory laparotomy was performed during which a left salpingo-oophorectomy was done, in addition to freeing of multiple pelvic adhesions. One month later she developed severe low pelvic pain and a right cystic adnexal mass (6 cm) was easily palpable. Due to this chronic problem she underwent a total abdominal hysterectomy and right salpingo-oophorectomy. One month later she developed left lower quadrant pain and a left lower pelvic mass was again palpated and treated with ovarian suppression. A year later she developed right lower quadrant pain and a pelvic mass was palpated and confirmed on ultrasound. Operation was performed during which a large pelvic mass was removed from the vaginal cuff with dissection of multiple pelvic adhesions. The presence of ovarian tissue was confirmed by pathologic examinations. Nine months later she underwent another exploratory laparotomy for symptoms of bowel obstruction. No mass was found and lysis of multiple intestinal adhesions was performed.

Three months later she returned, complaining of severe progressive dyspareunia. Large, bilateral, tender pelvic masses were easily palpable. Exploratory laparotomy revealed two large cystic masses that were removed. Pathologic diagnosis confirmed the presence of active ovarian tissue.

She was referred to us two weeks after operation. She had no complaints and a pelvic examination proved negative. The plasma estradiol level was 7 pg/ml. She was placed on a regimen of medroxyprogesterone acetate (Depo-Provera, 150 mg intramuscularly). Long-term suppression was planned with the need for further medroxyprogesterone acetate injections to be periodically evaluated by determinations of plasma estradiol levels. She again developed severe lower abdominal pain and dyspareunia and a right cys-

tic mass was felt attached to the vaginal cuff. The plasma estradiol level was less than 5 pg/ml but three days later she underwent a seventh laparotomy. A large cystic mass was removed from the right pelvis and multiple intestinal adhesions and numerous nodules were found throughout the abdominal and pelvic cavities. The pathologic diagnosis was "peritoneal cyst, foreign body reaction, chronic inflammation, fatty degeneration, and fibrosis." No ovarian tissue was identified. She has been kept on a regimen of medroxyprogesterone acetate, and the plasma estradiol levels have remained less than 5 pg/ml for the past four months.

Case 4. D. L., a 24-year-old, white woman, gravida 0, had a long history of recurrent ovarian cysts. A uterine suspension and left cystectomy were performed for a left pelvic mass, after which the patient was placed on a regimen of oral contraceptives (Ortho-Novum 1 + 50) for two years. Three months after stopping oral contraceptive therapy, she complained of abdominal pain. Laparoscopy revealed an 8 by 8 cm right follicular cyst from which 75 ml of blood was aspirated. Because of dense adhesions to the pelvic colon, no left adnexa could be clearly identified.

Two months later pain and a left adnexal mass developed. At laparotomy a large left ovarian cyst was found with dense adhesions to the colon and uterine wall. The cyst was multilocular with very thin walls and leaked a clear hemorrhagic fluid when incised. The left cyst was dissected from the ovary and an "endometrioma" removed from the right ovary. Pathologic findings revealed corpus hemorrhagica in the right sample and normal ovarian tissue with corpus albicans and hemosiderin deposit in the left. No endometriosis was found.

Five months later the symptomatology reappeared in the left lower quadrant. A blood sample was taken and sent to our laboratory. An elevated plasma estradiol level of 557 pg/ml was reported. Ovarian suppression with oral contraceptives was started. The patient became asymptomatic with plasma estradiol levels decreasing to 79 pg/ml in one month and to 24 pg/ml the second month.

Six months later ovarian suppression was terminated because of side effects. Following cessation of treatment, the patient again developed left lower quadrant pain and a palpable left ovarian cyst. An exploratory laparotomy (the fourth surgical procedure) revealed multiple pelvic adhesions, several left ovarian cysts (one measuring 5 by 7 cm), and complete obliteration of the architectural structure of the pelvic cavity. A complete loss of the adnexal anatomy on both sides without evidence of tubal patency prompted a total abdominal hysterectomy and bilateral salpingo-oophorectomy.

Eight months following operation the patient consulted our Section of Reproduction, complaining of similar symptomatology ongoing for the past few months. Plasma estradiol level was 272 pg/ml and a large left adnexal mass was palpated at that initial visit. A month later the plasma estradiol level was 234 pg/ml. Ovarian suppression was begun and the plasma estradiol level dropped to 7 pg/ml in 2 months. All symptoms disappeared and estradiol levels were maintained around 20 pg/ml.

Ovarian suppression was again interrupted because of side effects. Within a short time the left lower quadrant pain reappeared and the plasma estradiol level increased to 281 pg/ml. A soft, irregular mass could be felt in the left adnexal area. The patient refused further suppression and demanded a "final surgical solution." Exploratory laparotomy revealed a large, thin-walled, multiloculated cyst attached to the pelvic colon. The cyst along with periureteral tissue and a portion of the serosal peritoneum of the colon was removed in an effort to eliminate any remaining ovarian tissue. Five days after operation the estradiol level had dropped to 6 pg/ml. She was again placed on a regimen of ovarian suppression therapy.

Four months later the patient decreased the estrogen dosage in half because of weight gain. Three weeks later she developed progressive colic pain in the left costovertebral angle. She was admitted to the hospital with the diagnosis of kidney stone. An intravenous pyelogram showed possible external compression of the left ureter and mild left hydronephrosis. A large, very painful cystic mass fixed to the pelvic wall was palpated. A retrograde catheter was placed in the left ureter and her symptoms improved. The plasma estradiol level was 86 pg/ml and suppression with medroxyprogesterone acetate (Depo-Provera, 150 mg intramuscularly) and an oral contraceptive (Norlestrin, 2.5 mg twice daily) was started. A second intravenous pyelogram 7 days later revealed no further extrinsic compression of the ureter and a smaller and less painful mass was felt on pelvic examination. The patient was discharged on a regimen of oral contraceptives (Norlestrin, 2.5 mg/day) with a plasma estradiol level of 16 pg/ml and with plans for prolonged suppression with medroxyprogesterone acetate. She has remained asymptomatic for the past 4 months and monthly estradiol levels are between 14 and 18 pg/ml.

Comment

Patients with ovarian cysts are frequently found in clinical practice.[1] However, reports of ovarian cysts of the functional type are uncommon since the vast majority of these are asymptomatic and pass undiagnosed. Most regress spontaneously or after ovarian suppression never again to affect the patient.

The four patients described in this report present a similar, interesting, and unusual clinical syndrome characterized by the frequent recurrence of functional ovarian cysts. The cysts were symptomatic to the point of necessitating repeated surgical intervention and prolonged ovarian suppression with oral contraceptives. Each episode, characterized by pain and adnexal mass,

was accompanied by elevated plasma estradiol levels in three of the four patients in whom blood studies are available. The pathology report confirmed the presence of ovarian tissue in each case. During ovarian suppression, these patients remained asymptomatic, plasma estradiol levels were low, and the patients were free of pelvic masses.

Reports of recurrent ovarian cysts, such as those present in our group of patients, are most uncommon. Several explanations may be offered to elucidate the etiology of this syndrome. One causative factor may be an increased production of gonadotropins. It would appear that these ovarian cysts did not develop in response to elevated gonadotropins, as occurs in molar pregnancies, or from a complication of ovulation induction,[1, 2] since elevated gonadotropins were not found on any occasion. Whether a considerable rise in gonadotropin levels occurred before the appearance of the cysts is not known, since no hormonal levels were obtained prior to the patients' becoming symptomatic and since normal low levels of gonadotropins found during the cyst-free periods were the direct result of the ovarian suppression therapy. It is possible, therefore, that high gonadotropin levels may have initiated growth of the cysts and then decreased as a result of the elevated estrogen production by the cyst, at which time the patient sought consultation.

A second explanation may be that the ovarian tissue elicits a hypersensitive response to normal gonadotropins by forming these recurrent functional cysts. Such hypersensitivity of ovarian tissue could be due to an unknown error in the metabolic pathway of granulosa and/or theca cells. This hyperresponse to normal gonadotropin levels could be the counterpart of the unresponsive ovarian syndrome in which normal ovarian tissue does not respond to normal or increased gonadotropin levels.[5, 6] The mechanism by which normal-appearing follicles fail to respond to gonadotropins is not clear.

The above possibilities can be used to explain the clinical manifestations in Cases 1 and 2. However, they cannot provide the complete explanation of the recurrence of "ovarian-like" cysts following bilateral oophorectomy in Cases 3 and 4. The ovarian cellular composition of the recurring cysts along with the increased estrogen levels indicates that there is some ovarian or "ovarian-like" tissue within the pelvic cavity that responds to normal gonadotropin levels.

Ovarian tissue remaining within the pelvic cavity following bilateral oophorectomy could be a result of one of the following:

1. Incomplete surgical removal of the ovaries is a possibility since the oophorectomy was performed after several surgical procedures which have produced extensive pelvic adhesions and distortion of the normal position of the ovaries. However, this possibility seems remote since extreme caution was exercised at the time of oophorectomy and in the surgical procedures performed after bilateral oophorectomy to ensure complete removal of all ovarian tissue.

2. Accessory ovaries in which the extraovarian tissue is situated near to and usually connected with the normally placed ovary could be the source of the recurrent follicle cysts. Origin of such accessory ovaries is probably similar to that of the normally placed ovaries. Usually this accessory ovarian tissue is quite small and thus remains unrecognizable prior to pathologic evaluation. Wharton[7] in an excellent review article reported only 18 authors who had described this pathologic finding with only three seeing more than one case. In all of these cases tissue with the distinct structure and function of a normal ovary was present. Our two cases do not appear to be conditions of accessory ovaries since the cystlike structures were distant from and not connected to the site of the normal ovaries.

3. Another possibility involves the formation of extraovarian tissue not associated with the normally placed ovary. Wharton[7] described a rare condition called supernumerary ovary in which ovarian tissue was located in a position not associated with that of normally placed ovaries. These supernumerary ovaries may be functional. Kosasa and associates[8] reported on one patient with elevated total plasma estrogen after bilateral oophorectomy. The source of the estrogen was a retroperitoneally located supernumerary ovary. Wharton[7] theorized that such aberrant ovaries were the result of the failure of migrating germ cells to reach the developing genital ridge. That such germ cells do find their way to extragonadal areas and are viable and may be the source of tumors has been demonstrated in a variety of animal species.[9] Such primary germ cell tumors have been found in the anterior mediastinum[10] and in a retroperitoneal location.[11]

In our study, the pathologic findings show the cysts to contain granulosa luteal and theca luteal cells and ovarian stroma. No oocytes were observed. In association with Wharton's theory, presumably the extragonadal germ cells induced the surrounding mesenchymal cells to differentiate into ovarian cellular components. Another explanation would be that of Printz and associates[12] who reported a case of a 23-year-old, black woman in which they found ovarian tissue embedded in the omentum. They theorized that a portion of the genital ridge, after colonization by the germ cells, became detached and then reattached in a neighboring area. This would explain the normal ovarian

tissue contents of the cyst in the pathologic findings.

From our findings it appears that whatever the source of this ovarian tissue it becomes functional and produces large amounts of estradiol to levels much higher than those found after the removal of both normal ovaries. Such tissue may become extremely sensitive to circulating gonadotropins in the absence of normal ovarian tissue. Greenwald[13] showed in hamsters that after unilateral ovariectomy the remaining ovary hyperovulates. Biskind and Biskind[14] in rats and McLaren[15] in mice demonstrated that an ovary transplanted to the spleen hypertrophied only after the in situ ovary was also removed. Furthermore, Chihal and associates[16] demonstrated that "extraovarian" tissue affects the number of eggs ovulated and the plasma levels of progesterone in postpuberal rats receiving ovarian homografts. This has not been shown in humans; however, it is certainly possible that aberrant embryonic gonadal tissue in the absence of normal ovarian tissue may develop under the influence of normal gonadotropins and thus be responsible for recurrent ovarian cyst formation.

Infertility is an important secondary effect of either the syndrome or its long-term therapy. Only one of the patients presented here has been pregnant and this occurred prior to the development of the syndrome. Despite the desire for children in Patients 1 and 2, ovarian cysts have developed each time ovarian suppression was stopped.

The development of recurrent ovarian cysts either before or after bilateral oophorectomy is considered rare. It is possible that this syndrome may be more prevalent than a review of the literature leads one to believe. In fact, we have diagnosed four cases of this condition in the past two years.

The need for ovarian suppression and the monitoring of long-term therapy with plasma estradiol levels is recommended. Surgical approach to treat this syndrome does not seem adequate, and after the first recurrence probably no further surgery is indicated. Presently we find no alternative to ovarian suppression for the treatment of these patients. It is possible that this syndrome may regress after menopause, a time at which the ovary does not normally respond to markedly elevated gonadotropin levels.

We hope that by characterizing this syndrome we will encourage more reports of patients like these and therefore find a better way of evaluating and treating recurrent symptomatic functional ovarian cysts.

Optimum dosage of an oral contraceptive

A report from the study of seven combinations of norgestimate and ethinyl estradiol

JOHN S. LAWSON, M.S.*
S. EUGENE YULIANO, M.D.*
SAMUEL A. PASQUALE, M.D.
JENNIFER J. OSTERMAN, B.A.
Raritan, New Jersey

A statistically designed study was carried out to determine an optimum combination of norgestimate and ethinyl estradiol as an oral contraceptive, based on efficacy, safety, and side-effect patterns. A total of 1,991 patients were studied for more than two years while they were receiving various dosage combinations of these steroids. There were seven dosage combinations studied as part of a statistically orthogonal experimental design, augmented by three combinations near the center. The data arising from these studies were used to fit approximate functions relating the amount of norgestimate and ethinyl estradiol to the rate of spotting and breakthrough bleeding, gastrointestinal disturbance, and pregnancies. These functions, in turn, helped to identify an optimum dosage (0.125 mg. of norgestimate plus 0.035 mg. of ethinyl estradiol) in the entire range of combinations studied. (AM. J. OBSTET. GYNECOL. 134:315, 1979.)

THE MOST WIDELY USED oral contraceptives are combination products that consist of a synthetic estrogen and progestin. These drugs are extremely effective and possess a relatively high degree of safety. However, through the years there have been continued efforts to seek effective lower-dose forms of these drugs. In the late 1960's, researchers Inman and Vessey[1] in Great Britain, Sartwell and associates[2] in the United States, and others reported an association between the use of oral contraceptives and an increase in the risk of certain types of thromboembolic diseases. Later, Inman and associates[3] reported a positive correlation between the risk of these diseases and the dose of estrogen in an oral contraceptive. It has also been reported that certain side effects commonly attributed to the use of oral contraceptives (i.e., nausea, headache, nervousness) are related to the amount of estrogen in the contraceptive. In April, 1970, both the United States Food and Drug Administration[4] and the Medical Committee of the International Planned Parenthood Association[5] issued statements recommending the use of oral contraceptives containing the lowest effective levels of estrogen whenever possible.

Since 1970, there have been reports in the literature demonstrating the efficacy and side-effect patterns of oral contraceptives with dosages lower than those of previously marketed products. Bye and Elstein[6] and others[7, 8] have shown that combination contraceptives containing less than 0.05 mg. of ethinyl estradiol (EE) are effective in preventing pregnancies. One disadvantage to reducing the dosage of estrogen in oral contraceptives is the fact, reported independently in several articles,[7–9] that annoying intermenstrual bleeding, such as spotting or breakthrough bleeding (BTB), increases. Spotting and BTB rates are influenced not only by the amount of estrogen in an oral contraceptive but also by the ratio of the amounts of estrogen and progestin.[10] This makes the selection of an appropriate dosage for a low-dose oral contraceptive difficult.

There have been reports in the literature[7, 9] of clini-

cal studies comparing several regimens of lower-dose combination oral contraceptives for purposes of selecting an optimum combination and/or determining the relationship of bleeding patterns/efficacy to the dosage of the product. Because bleeding patterns are affected not only by the dosage of estrogen and progestin but also by the ratio of the two components, and since an optimum combination of two steroids may not be one of the regimens selected for a study, extremely sensitive study designs (i.e., selection of study regimens) and efficient methods of data analysis are needed for these types of studies. Application of statistica response surface methods[11] seems appropriate in this situation.

Response surface methods are a collection of mathematical and statistical procedures useful in studies where a response (numerical measure of the outcome of an experiment) is influenced by other independent variables that can be controlled. The procedures consist of experimental designs (i.e., methods for selecting several combinations of levels of independent variables for experiments), regression techniques (i.e., methods of fitting an approximate functional relationship between the response measurement and the independent variables), and mathematical procedures for exploring the fitted function or surface (i.e., predicting the response at levels of independent variables where no experiments have been conducted, finding the combination of minimum response, etc.).

For the problem of studying the effect of dosage in low-dose oral contraceptives, the independent variables are, of course, the dosage of estrogen and progestin, and the response may be pregnancy rate or severity of side effects (i.e., bleeding irregularities, gastrointestinal disturbance, etc.).

Material and methods

The purpose of this study was to determine the relationship between the dose of estrogen (EE) and progestin (norgestimate) in an oral contraceptive to the efficacy and side-effect patterns. Also, it was of interest to find the optimal combination of norgestimate and EE for the purpose of oral contraception. To accomplish this purpose, seven dosage regimens of norgestimate and EE were studied clinically. These regimens are listed in Table I.

The study was conducted in Mexico City, Mexico, between March, 1973, and December, 1974, and represents the effort of nine investigators. There were four separate protocols. The first protocol was an open study in which regimens A, B, C, G, and H were compared (Table I). The second protocol was a double-blind study in which regimen O was compared with regimen P (same dosage as C, Table I).

The third protocol was double blind and regimen T was compared with regimen R (same dosage as regimens C and P, Table I). The fourth protocol was an open study of regimen R.

Selection of patients for all protocols was determined by the following criteria: good general health, proved past fertility, absence of pregnancy, reproductive age (17 to 40 years), regular menstrual periods, and regular coitus. Patients who exhibited disorders commonly accepted as contraindicating sex hormone therapy, such as thrombophlebitis or thromboembolic disorders, pulmonary embolisms or cerebral apoplexy, cardiovascular disease, marked impairment of liver function, undiagnosed abnormal vaginal bleeding, known or suspected carcinoma of the breast or genital tract, history of any chronic disease, significant past or present illness, neurovascular lesions of the eye or visual disturbance, or a Class III or greater Papanicolaou smear, were excluded from the study.

Prior to admission, each patient had a complete history and physical examination, with special emphasis on breast and pelvic examinations. These examinations were repeated at approximately yearly intervals thereafter. In addition, routine laboratory and ophthalmologic examinations were performed on a subset of patients.

Upon entry into the study each patient was randomly assigned to one of the seven dosage regimens. The drug was administered orally as a 21 day cyclic regimen, three weeks with medication followed by one week without. Tablets were packaged in the manufacturer's Dialpak* tablet dispenser and patients returned after each cycle to obtain additional tablets. At each visit patients were interviewed and the blood pressure and weight were recorded. Any vaginal bleeding occurring on days of pill ingestion, which was not the result of the last menstrual period, was classified as spotting or BTB.

Some patients who were originally assigned randomly to one of the seven dosage regimens were later reassigned as new patients to the R regimen (0.125 mg. of norgestimate + 0.035 mg. of EE), since study on that regimen was continued after the other regimens were discontinued. Comparisons revealed no differences in the age distribution of patients studied in each regimen or the range and average of age at menarch, past pregnancies, and number of deliveries and abortions for patients in each regimen.

The data of interest, with respect to analysis, were counts of the number of cycles in which spotting or BTB occurred, percentage of patients with gastrointestinal disturbance during the first cycle of use, and number of pregnancies. Life-table[12] estimates of pregnancy rates were made and cycle percentages of spotting and BTB occurring in the stabilized region were calculated. With the minimum χ^2 estimation approach,[12–14] three response surfaces, or functions, were found, relating the cycle per cent of spotting and BTB, per cent of gastrointestinal disturbance, and the pregnancy rate to the estrogen and progestin dose. Empiric sampling studies have shown this approach to be good even in cases where failure rates are very low, as in the case of pregnancy rates in oral contraceptive studies.

Results

Table II shows the number of patients completing each cycle for each of the seven dosage regimens. The greater experience with regimens C, P, and R is due to the fact that regimen R was continued after study on the other regimens was stopped. Cycle control on all regimens was excellent, with an average cycle length of 28 days. The average number of days of flow (about 3.5 days) was almost identical for all regimens.

*Empiric adjustment to avoid nonzero pregnancy rates. See "Material and methods."

Since hormonal contraceptive treatment initially may cause slight physiologic changes, which later disappear or stabilize to some degree, the total cycle per cent of spotting and BTB in a study may be highly influenced by the amount of initial physiologic change and the average number of cycles per patient. Therefore, for purposes of comparing several dosage regimens, an estimate of the cycle per cent of spotting and BTB in the stabilized region would be more appropriate than the total cycle per cent. Estimates of the stabilized cycle per cent of spotting and BTB are presented by regimen in Table III.

The per cent of patients experiencing gastrointestinal disturbance during the first treatment cycle is also presented in Table III by regimen. Since the percentage of patients experiencing gastrointestinal disturbance after cycle one was very small in all seven regimens, it was thought that the first cycle per cent was appropriate for comparison between regimens.

Seven-month life-table estimates of the pregnancy rates per 100 women are shown in Table III. Seven-month rates were used since some regimens only had seven months of data available at the time of the analysis. Two of the regimens (B and H) studied had no observed pregnancies. In order to fit a response surface relating the life-table pregnancy rates to the dosage of the product, it was desirable to use only nonzero pregnancy rates (so that standard errors could be computed). To accomplish this, an empiric adjustment was made, similar to that proposed by Berkson,[15] in calculating the life-table rates for regimens B and H. These empiric pregnancy rates were 0.43 and 0.52, respectively.

Figs. 1 to 3 show three-dimensional representations

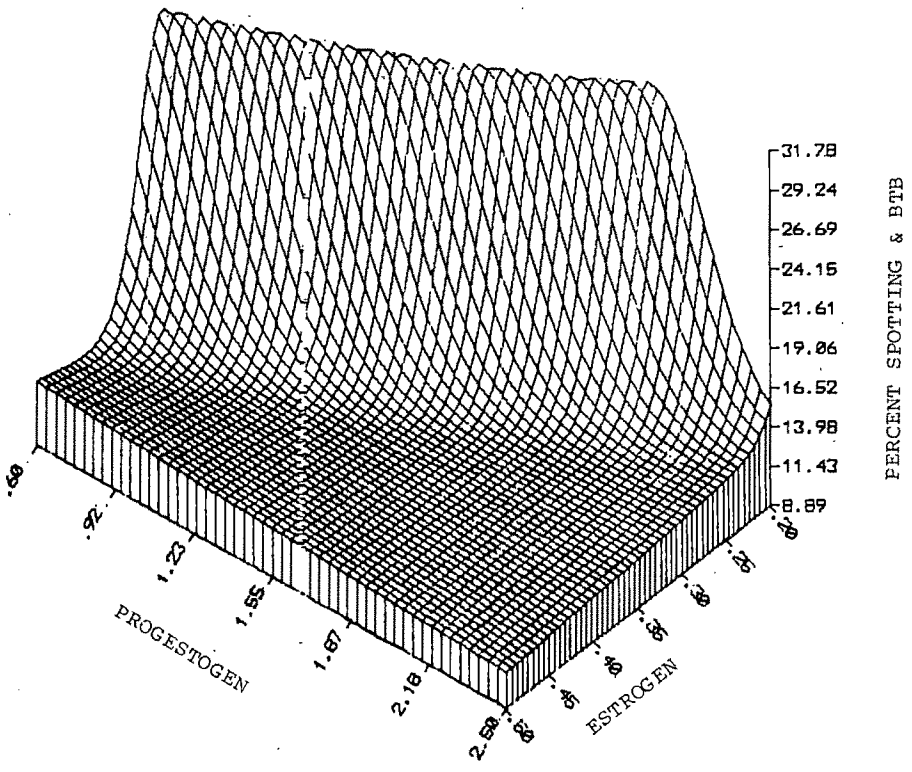

Fig. 1. Response surface for spotting and BTB combined.

of the fitted response surfaces for spotting and BTB, pregnancy rate, and per cent of gastrointestinal disturbance, respectively. Table III compares the fitted values (from the surfaces) to the observed values, and it can be seen that the fitted surface predicts the actual data rather well. The fitted values may be more reliable than the actual data since they combine the information from all the regimens in a cohesive manner. The response surfaces may also be used to predict the characteristics of dosage combinations not actually studied but still within the limits examined. Table IV, a semigraphic table, presents predictions for various alternate doses. It can be seen that slight reductions in either the progestin or estrogen doses from their levels in the C, P, and R regimens (i.e., 0.125/0.035) will significantly increase the amount of spotting or BTB and pregnancy rate.

Increasing the dose does not bring about a corresponding reduction in side effects or pregnancy rate. For this reason, the R regimen (0.125/0.035) was chosen as the optimal dosage of norgestimate and EE to be used in Phase III studies.

Comment

Examination of the response surface for spotting and BTB reveals that the amount of spotting and BTB is influenced, as others have reported, by the ratio of progestin and estrogen (i.e., more spotting and BTB at 0.060/0.050 and 0.250/0.020 than at 0.250/0.050). However, the major factor that seems to influence spotting and BTB in the low dose range is the absolute dose. As the dose of both estrogen and progestin is decreased, a much greater increase in spotting and BTB is observed than that produced by changing the ratio of the two components at higher doses.

The response surface for pregnancy rate shows that as the absolute dose of estrogen and progestin is reduced the pregnancy rate will increase in a smooth fashion. The upward twisting of the right side of the surface in the low-dose range indicates that the pregnancy rate is influenced more by the estrogen dose than by the progestin dose in low-dose combinations.

The low incidence of spotting and BTB for the lowest-dose combination (0.060/0.020) is difficult to explain; however, since there is a high pregnancy rate for that combination, it might be conjectured that this dosage was too low to prevent ovulation or provide sufficient exogenous estrogen to cause significant structural changes in the endometrium. The response surface for gastrointestinal disturbance clearly indicates that this side effect is almost totally estrogenically induced.

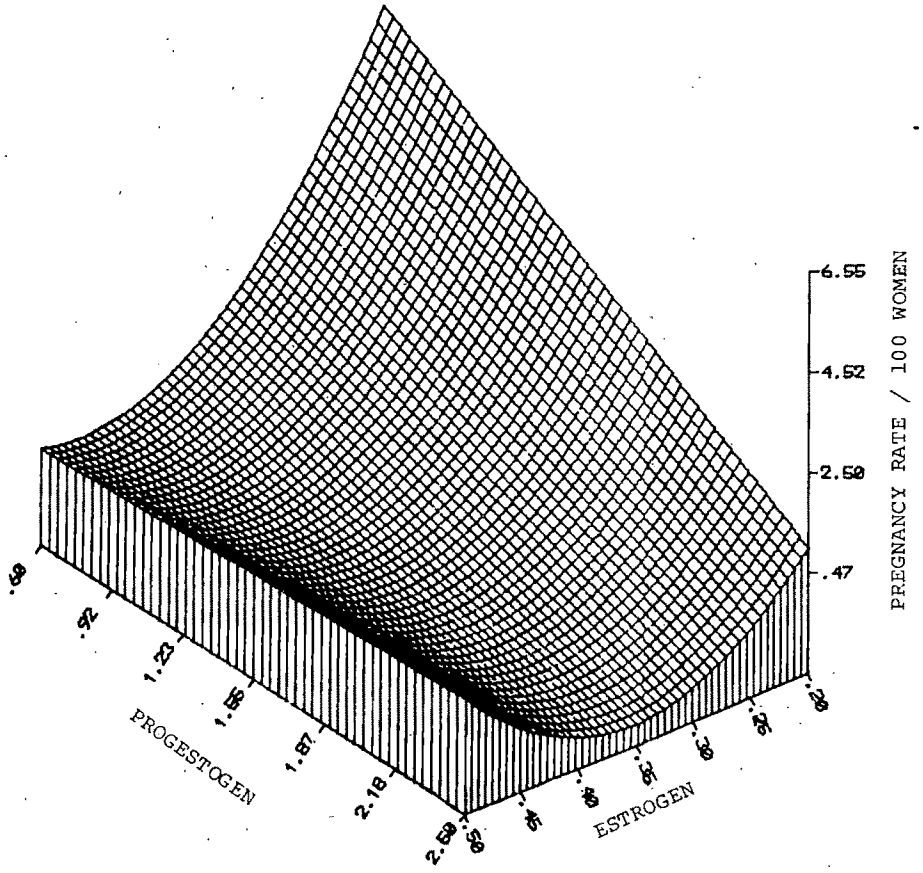

Fig. 2. Response surface for seven month pregnancy rate.

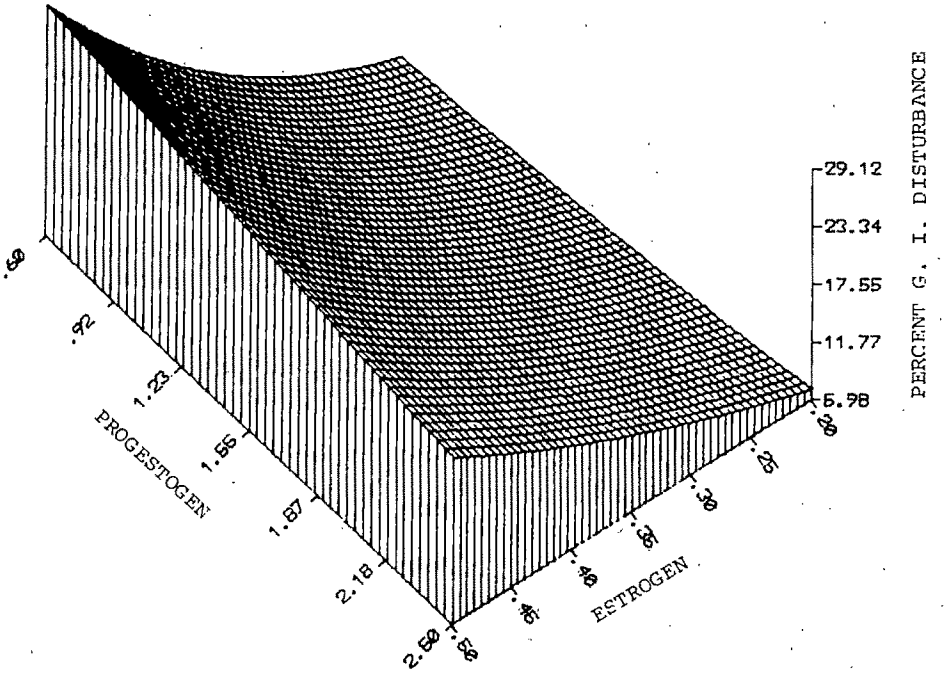

Fig. 3. Response surface for gastrointestinal disturbance.

Table IV. Effects of dosage changes (predicted values)

Effect	*Range*	*Differing estrogen dose*			*Differing progestin dose*		
		0.125/0.025	*0.125/0.035*	*0.125/0.045*	*0.100/0.035*	*0.125/0.035*	*0.150/0.035*
Pregnancy rate (7 mo.)	2.0-5.00	3.2					
	1.0-1.99				1.2		
	0.0-0.99		0.67	0.45		0.67	0.50
Spotting and BTB	14.1-20.0	17.8			18.2		
	12.6-14.0						
	10.0-12.5		12.0	11.5		12.0	11.4
Gastrointestinal disturbance	15.1-25.0			22.4			
	10.1-15.0		14.7		14.4	14.7	15.0
	0.0-10.0	9.3					

Simultaneous consideration of all three response surfaces has clearly indicated that the 0.125/0.035 dosage combination is minimal in some respects. Further reduction of either estrogen or progestin, with the other component unchanged, would be expected to result in an increased pregnancy rate and intermenstrual bleeding. The estrogen dose could be reduced without seriously changing the characteristics of the contraceptive by increasing the dose of progestin. For example, a 0.180/0.030 combination would probably be reasonable. On the other hand, the progestin dose could be reduced by increasing the estrogen dose and a 0.090/0.040 combination would probably have comparable characteristics in the same population of women.

In summary, it is believed that the examination of several appropriately selected dose regimens and the fitting of response surfaces to the observed efficacy and side-effect indicators has clarified the relationship between dosage, efficacy, and safety of a potential combination oral contraceptive containing 0.125 mg. of norgestimate and 0.035 mg. of EE, thus making the choice of an optimal dosage easier.

Ovum transport in women treated with methyl ergonovine

ENRIQUE GUILOFF, M.D.

The location of ova in the genital tract was studied between 24 and 120 hours after the luteinizing hormone (LH) surge in 32 women who had been treated with methyl ergonovine in doses known to stimulate tubal contractility. Thirteen eggs were found in the fallopian tubes, between 48 and 120 hours after the LH peak, and no eggs were recovered from the endometrial cavity. No significant difference in tubal ovum recovery or in tubal segmental distribution of ova was found in comparison with these parameters in an untreated control group. These results indicate that stimulation of tubal contractility with methyl ergonovine does not accelerate ovum transport through the fallopian tubes in the human. (AM. J. OBSTET. GYNECOL. 134:321, 1979.)

A NUMBER OF drugs can modify tubal contractility in the human as shown by intraluminal pressure recordings. In previous work[1] we have shown that methyl ergonovine can induce long-lasting tubal contractions. After a single dose of 0.2 mg intramuscularly, a latency period of 90 to 120 seconds is followed by hypercontractility which lasts for nearly 4 hours. A clear dose-response relationship was also demonstrated.

Recent information[2] indicates that unfertilized ova in women reach the uterine cavity around 80 hours following ovulation. It is generally believed that ovum transport is accomplished by the mechanical interaction of tubal smooth muscle and ciliary activity. Therefore, it is logical to assume that the rate of ovum transport can be modified by drugs which stimulate tubal contractility.

The purpose of this study was to determine whether or not the increased tubal contractility induced by methyl ergonovine results in accelerated passage of the ovum through the fallopian tubes.

Material and methods

This study included 50 healthy, fertile women, without contraceptive treatment during the month preceding the cycle studied. These women had been accepted for surgical sterilization by the Ethics Committee of the Department of Obstetrics and Gynecology of the J. J. Aguirre Hospital.* Each subject underwent a careful study of her obstetric and medical history and was given information on the nature and purpose of this study. Informed consent was obtained prior to admission to the study. All subjects were instructed to avoid intercourse during the study cycle, and this was controlled by daily examination of cervical mucus.

Blood was drawn daily between 9 and 10 A.M. starting 6 days before the expected day of ovulation until the day of operation and immediately assayed for es-

*The investigators from the Pontificia Universidad Católica de Chile do not belong to this Committee and had no participation in the clinical aspect, in the selection of patients, or in the surgical sterilizations which were done in J. J. Aguirre Hospital.

trogen content by a rapid radioimmunoassay.[3] The preovulatory estrogen peak was used to time drug administration and operation. The remaining plasma was stored at −20° C for subsequent radioimmunoassay of luteinizing hormone (LH) and progesterone. Methyl ergonovine, 0.2 mg intramuscularly, was administered every 4 hours. The initiation of treatment in relation to LH peak and the number of injections given are shown in Table I.

In all cases operation was performed with spinal anesthesia between 24 and 120 hours following the LH surge and included the following steps: (1) laparotomy; (2) inspection of ovaries, to determine if ovulation had occurred, the ovulatory side, and the number of rup-

tured follicles; (3) placement of five ligatures along the tube to divide the lumen in four equal segments and prevent major displacement of the ovum during further manipulation of the organ; (4) salpingectomy; (5) removal or ligation and sectioning of the contralateral tube; (6) transfundal flushing of the endometrial cavity.

The tubes were sectioned at the site of each ligature and each segment was flushed separately with Tyrode's solution. All flushings were distributed in embryologic culture dishes and examined at low magnification to search for eggs. When the ovum was recovered the interval between the LH peak and recovery was expressed in multiples of 24 hours. LH was measured as described in Midgley.*[4] Progesterone was measured by radioimmunoassays, as described by Thorneycroft and Stone.[5]

A schematic drawing of the experimental design is shown in Fig. 1.

The results obtained in women treated with methyl ergonovine were compared with those of a control group previously reported.[2]

Results

Eighteen patients were eliminated from the study for the following reasons: anovulatory cycles, anatomic alterations of internal genitals, or presence of preovulatory follicles at the time of operation. In the 32 remaining patients the presence of a corpus luteum was confirmed macroscopically and microscopically.

As shown in Table I and Fig. 1 treatment with methyl ergonovine was initiated before ovulation in 12 patients and after ovulation in 20 patients. Ovulation was assumed to have occurred 17 hours following the LH peak, on the basis of previous observations.[6] In both groups the frequency of ovum recovery was similar; therefore, they were analyzed as a single group.

Ovum recovery according to the intervals between LH peak and operation and in comparison with a control group is shown in Table II. Thirteen ova were found in 32 treated subjects. All of them were recovered between 48 and 120 hours following LH peak and were located in the fallopian tube. The rate of ovum recovery from the fallopian tubes between 24 and 120 hours was 40.6% in the treated group and 39.6% in the control group.

The distribution of ova in the four tubal segments studied is shown in Fig. 2. In the control group there was a marked tendency of ova to be located in the middle quarters, regardless of time after LH peak.

*The reagents for measurement of LH were a gift from the National Institute of Arthritis, Metabolism and Digestive Diseases, National Pituitary Agency.

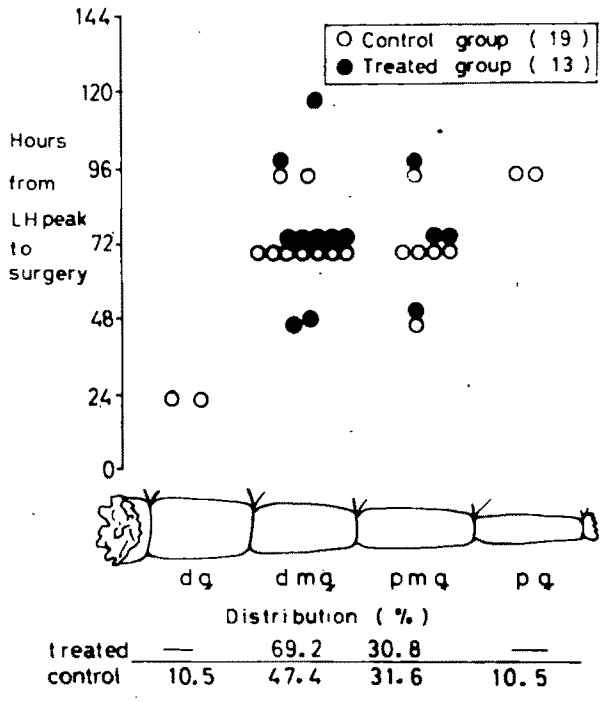

Fig. 2. Segmental distribution of ova in the fallopian tubes in control[2] and treated groups according to the time from LH peak to operation. *dq* = Distal quarter; *dmq* = distal middle quarter; *pmq* = proximal middle quarter; *pq* = proximal quarter.

Only 20% of ova were found in the extreme quarters. In the treated group all ova recovered were located in the middle quarters. The two distributions are not statistically different.

Comment

The purpose of this investigation was to assess the influence of increased tubal contractility produced by methyl ergonovine upon ovum transport through the fallopian tubes. The study was designed to test the hypothesis that increasing contractility could lead to accelerated passage of the ovum. This is reflected in the fact that ovum search was done in 28 of the 32 patients at a time when ova are normally found in the fallopian tubes. The comparison of ovum recovery from the tubes in treated and control subjects suggested that hypercontractility was not associated with premature passage of ova into the uterus. This was further substantiated by the fact that not a single ovum was recovered from the uterine cavity in 26 cases in which the cavity was flushed within the first 96 hours following the LH peak.

The distribution of ova among four tubal segments of the treated group was compared with that of a control group. This comparison showed that treatment

with methyl ergonovine failed to displace the ovum toward a more proximal position.

Contrary to our expectation the data presented clearly show that hypercontractility of the fallopian tubes induced by methyl ergonovine is not associated with acceleration of ovum transport.

The possibility of delayed passage of the ovum into the uterus as a consequence of treatment was not investigated in the present study since only four subjects were operated upon at a time when ova normally would have been recovered from the uterus.

The fact that ova were recovered from neither the tubes nor the uterus in three of those cases is within the method error but is compatible also with normal tubal transport followed by rapid expulsion from the uterus. This possibility should be kept in mind since methyl ergonovine at the doses given also stimulates contractility of the nonpregnant uterus.

The single ovum recovered from the fallopian tube 120 hours following the LH peak suggests that tubal locking of ova could be associated with hypercontractility.

Effect of dexamethasone on gonadotropin responsiveness to luteinizing hormone–releasing hormone and clomiphene in women with secondary amenorrhea

JAMES R. SOWERS, M.D.
JAMIL FAYEZ, M.D.
Kansas City, Missouri

We have studied the effects of administration of dexamethasone, 2 mg orally every 6 hours, for 5 days on the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) induced by luteinizing hormone–releasing hormone (LHRH) in six women with secondary amenorrhea and on the release of these gonadotropins induced by clomiphene citrate in 10 women with secondary amenorrhea. Dexamethasone suppressed baseline serum levels of LH and FSH and blunted the LHRH-induced release of LH and FSH in six women. Following dexamethasone administration, the LH and FSH response to clomiphene citrate, which competes for gonadal steroid receptor binding sites in the hypothalamus, resulting in increased release of LHRH, was blunted in the 10 women studied. The data indicate that short-term administration of pharmacologic doses of glucocorticoids suppresses the secretion of LH and FSH by a direct effect on the anterior pituitary and possibly by an effect at the suprahypophyseal level with inhibition of release of LHRH. (AM. J. OBSTET. GYNECOL. 134:325, 1979.)

IT HAS BEEN PREVIOUSLY observed that women experience disorders of menstruation when receiving glucocorticoids.[1] Evidence from animal studies suggests that the suppressive effects of glucocorticoids on the hypothalamic-pituitary axis are exerted by impairment of gonadotropin secretion by a direct action on the anterior pituitary or by their effects at the suprahypophyseal level with inhibition of release of luteinizing hormone–releasing hormone (LHRH).[2–4] One prior report indicated that short term administration of dexamethasone did not result in suppression of basal levels of follicle-stimulating hormone (FSH) in man.[5] Long-term administration of glucocorticoids has been shown to suppress basal and midcycle luteinizing hormone (LH) peak levels in normally cycling women[6] and to suppress the LH response to LHRH in women with disorders of menstruation.[1]

The present study was performed to determine the effects of short-term administration of high doses of glucocorticoids on LH and FSH responses to LHRH and clomiphene in women with secondary amenorrhea.

Material and methods

Sixteen women (aged 21 to 37 years) with secondary amenorrhea and infertility were studied. The subjects had normal serum prolactin levels, normal lateral skull films, and normal visual fields and none had galactorrhea. Most of these patients were obese; they had high normal LH and normal FSH levels and slightly elevated serum testosterone and urinary 17-ketosteroid levels. The diagnosis of polycystic ovary disease was confirmed at laporoscopy in four of the subjects.

LHRH studies. Six women (aged 23 to 37) were given an intravenous bolus of 100 μg of LHRH at 0800 hours before and after they received dexamethasone, 2

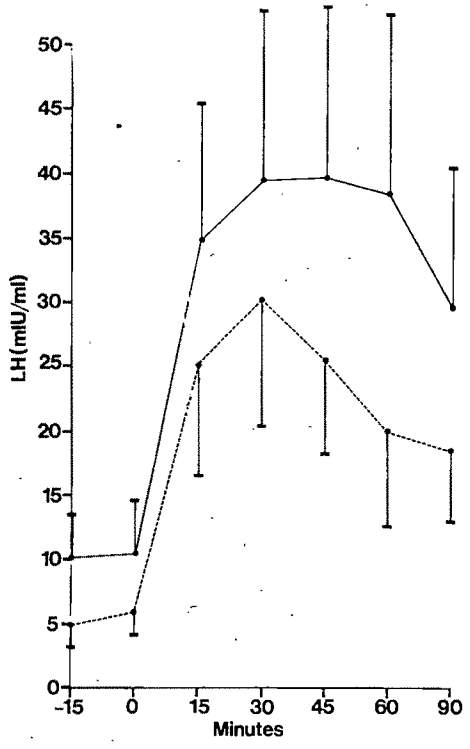

Fig. 1. Mean serum LH responses to LHRH (given at 0 time) in six women with secondary amenorrhea before (solid line) and after (broken line) dexamethasone administration; vertical bars show standard errors of the means.

mg orally every 6 hours for 5 days. Baseline samples of blood (−15 and 0 minutes) were drawn through an indwelling 19 gauge needle and further blood samples were obtained at 15, 30, 45, 60, and 90 minutes after injection of LHRH.

Clomiphene studies. Ten of the subjects (aged 21 to 34) were given 100 mg of clomiphene citrate orally for 5 days. Two weeks later the subjects received 100 mg of clomiphene citrate daily with simultaneous administration of dexamethasone, 2 mg orally every 6 hours for 5 days. On each occasion three blood samples were drawn at 0800, 0900, and 1000 hours prior to (day 1) and after (day 6) clomiphene citrate administration.

Radioimmunoassays. Serum was stored at −20° C and all LH and FSH samples from each study were measured in duplicate in one assay to avoid interassay variation. Serum levels of LH and FSH were measured by double-antibody radioimmunoassays; human antipituitary preparation LE-907 supplied by the National Pituitary Agency was used as the assay standard.[7] The lower limits of sensitivity were 1.0 mIU/ml for LH and 0.5 mIU/ml for FSH. The within-assay coefficients of variation were 5.1% for LH and 4.9% for FSH.

Statistics. Statistical comparisons of serum hormone

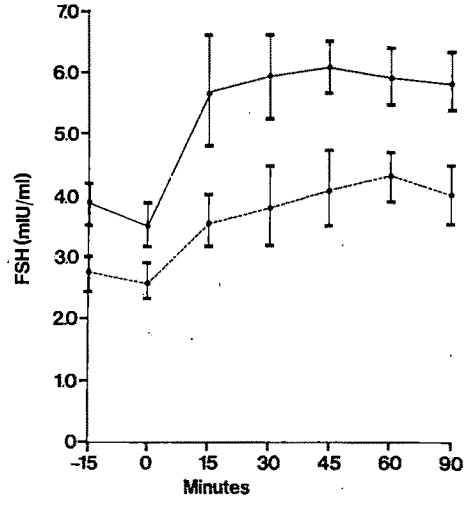

Fig. 2. Mean serum FSH responses to LHRH (given at 0 time) in six women with secondary amenorrhea before (solid line) and after (broken line) dexamethasone administration; vertical bars show standard errors of the means.

responses to LHRH and clomiphene before and after dexamethasone administration were made with Student's paired t test.

Results

The average basal (mean of −15 and 0 values) serum LH level for the six women receiving LHRH was significantly less ($p < 0.025$) after administration of dexamethasone (5.5 ± 2.5 mIU/ml) than with no pretreatment (10.2 ± 3.7 mIU/ml) (Fig. 1). The mean serum LH response to LHRH in the six women after dexamethasone was less ($p < 0.05$) at the sampling times of 15, 45, 60, and 90 minutes after LHRH administration than the response with no dexamethasone pretreatment (Fig. 1). Dexamethasone administration resulted in a reduction ($p < 0.01$) in the average basal serum FSH value from 3.7 ± 0.3 mIU/ml to 2.7 ± 0.3 mIU/ml (Fig. 2). The FSH response to LHRH in these six women was less ($p < 0.005$) after dexamethasone pretreatment at all sampling times from 15 through 90 minutes after LHRH administration.

Table I shows that administration of dexamethasone in 10 subjects resulted in a reduction ($p < 0.01$) in the incremental LH and FSH responses to clomiphene citrate.

Comment

In this study basal levels of LH and FSH were clearly lowered by short-term administration of high doses of dexamethasone, which is in agreement with a previous observation in young women[6] and which differs from

the previous report of no suppression by glucocorticoids of FSH levels in young men.[5] These observed differences in the effects of glucocorticoids on basal LH and FSH secretion are probably related to dose and duration of administration and to sexually related differences in sensitivity to glucocorticoid suppression. Sowers and co-workers[8] have previously shown that short-term high-dose dexamethasone administration suppresses basal thyroid-stimulating hormone (TSH) and prolactin (PRL) secretion in man. The results of these studies may indicate that pharmacologic doses of glucocorticoids exert a general inhibitory effect on the basal secretion of anterior pituitary hormones.

The observation in this study that short-term administration of high doses of dexamethasone suppresses the LH and FSH response to LHRH and clomiphene is consistent with prior observations in women receiving long-term glucocorticoid therapy.[1] The findings in these studies indicate a direct inhibitory effect of glucocorticoids at the level of the anterior pituitary. Clomiphene citrate stimulates gonadotropin secretion, probably by competing for gonadal steroid binding sites in the hypothalamus, thus blocking the negative feedback action of estrogen on LHRH secretion.[9] Our observation that dexamethasone administration inhibits the LH and FSH response to clomiphene suggests that glucocorticoids may also act at the level of the hypothalamus to inhibit the release of LHRH. In support of this concept is the previous observation that cortisol implants in the medial basal hypothalamus in immature rats delay sexual maturation,[10] suggesting an action of glucocorticoids at the suprahypophyseal level. However, the blunted gonadotropin response to clomiphene that we observed could also represent direct inhibition by glucocorticoids at the level of the anterior pituitary.

In man glucocorticoids exert suppressive effects at the hypothalamic-pituitary level not specific to the adrenocorticotropic axis. Glucocorticoids suppress hypoglycemia-induced growth hormone release,[11, 12] eliminate the periodicity of TSH secretion,[13] and blunt the TSH and PRL response to thyrotropin-releasing hormone.[8, 14, 15] We further observed that glucocorticoids lower basal secretion of LH and FSH and blunt the gonadotropin response to LHRH and clomiphene in women with disorders of menstruation. However, these observations may not be applicable to women with normal menstrual cycles.

The authors wish to thank Ms. Jean Graeff for the preparation of the manuscript.

A practical treatise on inflammation, ulceration, and induration of the neck of the uterus: with remarks on the value of leucorrhoea and prolapsus uteri as symptoms of uterine disease

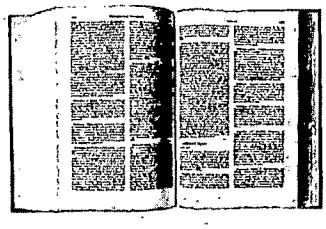
JAMES HENRY BENNET
London, John Churchill, 1845

60 INFLAMMATION, ULCERATION, AND

blood, occasional flooding, indurated, lobulated, and ulcerated cervix; that it was with difficulty I could form a correct diagnosis. This may be done, however, if we attend to the history of the patient, and examine minutely the local state of the uterine organs. The origin of the disease may be always traced to difficult parturition. The fissures divide the cervix into lobules, but each lobule is itself smooth and round, however indurated it may be. These fissures radiate from the os. The vagina is perfectly free, at its union with the cervix, which is seldom the case in advanced ulcerated cancer. Moreover, in these extreme cases, the inflammation always extends deeply into the tissue of the uterus, the volume of which is increased. By pushing back the posterior or anterior cul de sac of the vagina with the pulp of the index finger, it is not difficult to ascertain whether or not the induration of the cervix extends to the posterior or anterior plane of the uterus. In order to ascertain whether the volume of the uterus itself is increased, one or two fingers of the right hand must be introduced into the vagina, the pulp of the fingers directed towards the pubis of the patient. The fingers

INDURATION OF THE CERVIX UTERI. 61

being then placed underneath the cervix, and the posterior vaginal cul de sac pushed back, it is very possible to fix or to raise the uterus by them. If the left hand is placed at the same time on the hypogastric region immediately above the pubis, and the patient is told to relax the abdominal parietes, the abdomen may be depressed over the uterus, so as for the latter organ to be distinctly felt between the finger or fingers in the vagina, and the hand over the pubis. Its volume may thus be very accurately appreciated. The ovaries, lateral ligaments, indeed, the entire pelvic cavity, may be explored in this way with the greatest ease. It is, however, absolutely necessary, to accomplish this exploration satisfactorily, that the examination should be made whilst the patient is lying on her back. The two hands could not be used freely if the patient were placed on her side, as is usually the case in this country.



Speculum.—The speculum reveals still more plainly the state of things. When the cervix has become the seat of inflammatory induration, whether caused or not by the ulceration, the existence of the induration tends to keep up the ulceration, and will invariably reproduce it if the latter be

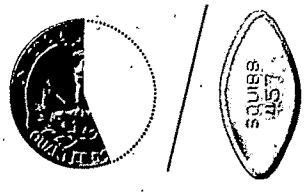
Until the advent of cellular pathology the differentiation between benign and malignant uterine tumors presented a vexing problem for physicians who used the term "mole" for both until the mid–nineteenth century. Bennet, of London, first presented criteria to distinguish clearly between malignant and nonmalignant uterine neoplasms. His treatise was based on his seven years' experience as pupil and later "intern" and "resident medical functionary" in the hospitals of Paris and primarily was concerned with inflammation and ulceration of the uterine cervix. He wrote in the preface: "... I was compelled to analyze carefully the morbid phenomena of every case, so as to satisfy the inquiring disposition ... I was thus soon to perceive, that however carefully the field of uterine pathology had been investigated, there still remained much to be elucidated." During this period vaginal examination of women with uterine disorders was infrequently carried out, and it was Bennet, in England, who popularized the use of the speculum, which had been described by Joseph C. A. Récamier only a few years previously. Bennet described in great detail the normal cervix and

0002-9378/79/110329+02$00.20/0 © 1979 The C. V. Mosby Co.

its variants in both nonparous and parous women. "The size and length of the cervix uteri vary considerably in different females. Indeed, these physiological variations are so great, that were we to allow curselves to be guided by size alone . . . we should, undoubtedly, be often misled, and induced to suppose that disease existed when it did not." He maintained that leukorrhea was a result of inflammation of the cervix or endometrium "endometritis") rather than being a primary disease in itself. "If, however, a wide, thick stream of muco-pus issues deeply from between the lips, it probably originates in the uterine cavity, and the membrane which lines it is most likely inflamed." Bennet taught that infertility commonly resulted from inflammation and ulceration of the cervix. "In nearly all, and perhaps in all the cases which I have narrated, the females affected, although exposed to sexual intercourse, remained sterile during the entire duration of the disease; in some, a period of many years." He also observed that such inflammations were much more common in multiparous patients and, in fact, that "the state of pregnancy itself predisposes to such inflammation and ulceration . . ." In addition he also described syphilis of the cervix, a relatively uncommon lesion as compared with chancre of the vulva or vagina, and presented criteria for distinguishing this from other ulcerations. Bennet described the marked increase in blood supply to the uterus during pregnancy: ". . . the entire organ becomes one of the most instead of one of the least vascular in the human economy." The majority of Bennet's monograph treats the cervix and its diseases, both benign and malignant, and includes 18 case reports to illustrate his points. Perhaps one of his more important contributions was to distinguish by visual and tactical examination between benign and malignant disease of the cervix. In benign conditions: "the fissures divide the cervix into lobules, but each lobule is itself smooth and round, however indurated it may be . . .. The vagina is perfectly free, at its union with the cervix, which is seldom the case in advanced ulcerated cancer . . .." He continued by describing in detail various manifestations of cervical cancer, such as corroding ulcer, cauliflower excrescence, scirrhous form, and others. Bennet noted that it was not hardness of the cervix that distinguished cancer, ". . . but the irregularity of the hardened surface, and the existence of the tubercles, which project here and there," and confessed that "there are, nevertheless, instances in which the distinction is difficult to make, when the cervix has been deeply fissured by difficult labours or miscarriages . . .. In such instances, the indurated organ may be divided into several lobes, and present an uneven, and apparently irregular surface, although merely chronically inflamed. On a closer examination, however, it will be found that the fissures which separate the lobes radiate around the cavity of the os as a centre, which is not the case in cancerous tumors, and that each separate lobe is perfectly smooth in itself, and free from tubercle or superficial inequalities. If these data were generally known, and always kept in mind, errors of diagnosis in the first stage of the disease would seldom be made; but I believe that such is not the case, and that mere induration of the cervix, particularly if the organ is lobulated, is not infrequently taken for cancer, and treated as such. When this occurs, it is not surprising that the disease should give way under rational treatment, and that practitioners who fall into this error should conscientiously be able to bring forward cases to prove that they have cured incipient cancer . . .. When once ulceration has occurred, the diagnosis becomes much easier . . . there is generally loss of substance; the ulcerated surface is also hard, and presents numerous lobules, tubercles, hard ridges, disseminated with the utmost irregularity, and presenting, as a rule, that stony hardness which is only occasionally met with an inflammatory induration." He presented many treatments for the various benign cervical inflammations and ulcerations. Bennet's insistence that inflammation of the cervix was the prime uterine affection that led to associated problems, including prolapse, menstrual irregularities, parametritis, pelvic pain, bladder irritation, etc., and that these could be cured by local treatment of the cervix (including bleeding by leeches), led mid–nineteenth century gynecologists to a renewed attack on cervical disease with various caustics, tinctures, and emollients. Although a true distinction of malignant and nonmalignant cervical and uterine lesions had to await Rudolf Virchow, Bennet, by helping to differentiate benign from malignant uterine disease, made possible a rational surgical approach to uterine tumors. A second edition of Bennet's work, more than doubled in size, appeared in 1849, and this was followed by two subsequent English editions as well as translations into French and German. For many years Bennet served as one of the editors of the *Lancet*. Because of chronic pulmonary disease, he retired to the French Riviera where he continued to write, one of his important works being "Treatment of Pulmonary Consumption by Hygiene, Climate and Medicine."

Good reasons to look at MYCOSTATIN® Vaginal Tablets (Nystatin Vaginal Tablets U.S.P.) again

Little or no resistance



"Repeated subculture of *Candida albicans* in increasing concentrations of nystatin results in little or no development of resistance..."[1] No occurrence of *in vivo* resistance as a general rule.

Virtually nontoxic and nonsensitizing

The manual application option

The fact that a vaginal tablet can be inserted *without* an applicator offers an important option when such a method is deemed advisable by the physician.

Economy

Your patients can save substantially compared to the cost of Miconazole Nitrate Cream or Clotrimazole Vaginal Tablets.*

Mycostatin® Vaginal Tablets

Nystatin Vaginal Tablets U.S.P.

[1]Goodman & Gilman, *The Pharmacological Basis of Therapeutics*, 5th Ed, 1975, p. 1236.
*Based on manufacturers' published prices to retailers.

See following page for brief summary.

MYCOSTATIN® Vaginal Tablets
Nystatin Vaginal Tablets U.S.P.

MYCOSTATIN® VAGINAL TABLETS
Nystatin Vaginal Tablets USP

DESCRIPTION: Mycostatin Vaginal Tablets (Nystatin Vaginal Tablets USP) are provided as diamond-shaped compressed tablets containing 100,000 units of nystatin dispersed in lactose with ethyl cellulose, stearic acid, and starch.

INDICATIONS AND USAGE: This product is effective for the local treatment of vulvovaginal candidiasis. Confirm diagnosis by KOH smears and/or cultures prior to therapy. Rule out Trichomonas and *H. vaginalis* by appropriate laboratory methods since these pathogens do not respond to nystatin.

CONTRAINDICATIONS: Contraindicated in patients with a history of hypersensitivity to any of the components of the tablets.

PRECAUTIONS: General—Discontinue therapy if sensitization or irritation is reported during use.

Laboratory Tests—Repeat microbiological studies to confirm diagnosis and rule out other pathogens before instituting another course of antimycotic therapy if there is a lack of response to nystatin vaginal tablets.

Usage in Pregnancy—No adverse effects or complications have been attributed to nystatin in infants born to women treated with nystatin vaginal tablets.

ADVERSE REACTIONS: Nystatin is virtually nontoxic and nonsensitizing and is well tolerated by all age groups, even on prolonged administration. Rarely, irritation or sensitization may occur (see Precautions).

For full prescribing information, consult package insert.

HOW SUPPLIED: Available in packages of 15 and 30 individually foil wrapped tablets with applicator and in Unimatic®cartons of 50 single-dose packs per carton—each cello-protected single-dose pack consists of one individually foil wrapped tablet, one applicator, and one "Instructions for the Patient" leaflet.

FACULTY POSITIONS

There are currently openings for full-time faculty in Obstetrics and Gynecology who have Board certification or eligibility. Teaching, research and patient care interests important. Special training and expertise in maternal and fetal medicine, reproductive endocrinology, gynecologic oncology or ambulatory care is desired. Academic rank and salary are dependent on qualifications. If interested, please send curriculum vitae and bibliography to:

William N. Spellacy, M.D.
Professor and Head
Department of Obstetrics & Gynecology
Abraham Lincoln School of Medicine
University of Illinois Medical Center
840 South Wood Street
Chicago, Illinois 60612

(Affirmative Action/Equal Opportunity Employer)

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.95 each, postpaid (3 for $14., 6 for $24.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

Jesse Jones Box Corporation (est. 1843)
P. O. Box 5120
Philadelphia, Pa. 19141

Please send me, postpaid ____ library cases for AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY at $4.95 each (3/$14., 6/$24.)

☐ **NEW SIZE (8¼" × 11") 3 cases/year**
☐ **OLD SIZE (7¼" × 10½") copies prior to 1975 (2 cases/year)**

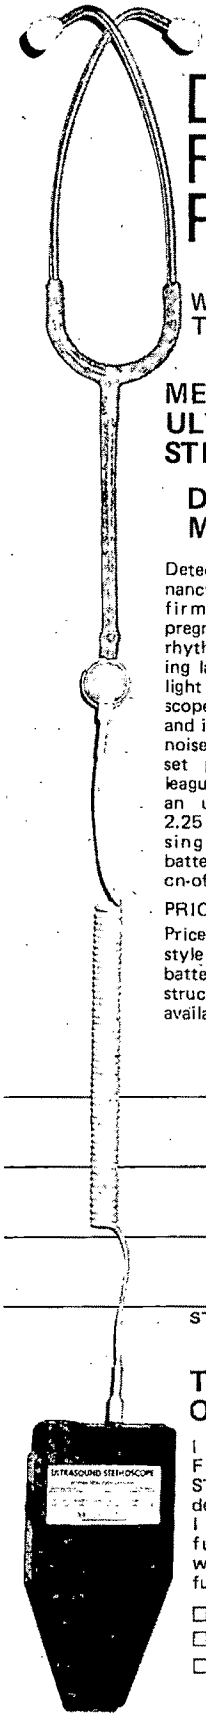
DIRECTOR OBSTETRICS AND GYNECOLOGY



Full time, Waterbury Hospital. Yale University Affiliated 500 bed teaching hospital. To direct training of Yale Obs/Gyn residents and medical students. To help ensure high quality of patient care. To coordinate continuing education for physicians in practice. Hospital also has residency programs in Medicine, Surgery, Pediatrics, Radiology, Urology and Orthopedics with relationships with Yale or University of Connecticut. Medical students from Yale, U. Connecticut, Dartmouth, other schools receive training at W.H. Salary competitive, excellent fringe benefits, referral private practice permitted. Yale Clinical Faculty Appointment. Prerequisites: Academically oriented, board certified skilled clinician and teacher with administrative experience and/or ability. Three or more years experience as full time or clinical faculty member of a medical school. Some practice experience desirable. For further details send CV to: Thomas T. Amatruda, Jr., M.D., Clinical Director, Waterbury, CT 06720. W.H. is an equal opportunity employer.

MATERNAL – FETAL MEDICINE

Opening for Obstetrician with eligibility for certification by the American Board of Obstetrics and Gynecology with special interest in Maternal-Fetal Medicine. Large clinical service with time for basic science or clinical research. For further information contact:

Preston V. Dilts, Jr.,
Professor and Head,
Department of Obstetrics and Gynecology,
University of Tennessee,
Center For Health Sciences.

The University of Tennessee is an equal opportunity/affirmative action employer.

DETECT FETAL PULSE

WITH THE

MEDASONICS ULTRASOUND STETHOSCOPE®

Doppler Model FP3A

Detects fetal life early in pregnancy (9-12 weeks) • Confirms fetal life throughout pregnancy • Assesses rate and rhythm of the fetal heart during labor • Pocket size; small, light and durable • Stethoscope style headset for privacy and isolation from background noise • Jack for second headset permits patient or colleague to listen • Operates at an ultrasound frequency of 2.25 MHz • Powered by a single long-life, replaceable battery • Two simple controls; on-off switch and volume.

PRICE $385

Price includes one stethoscope style headset, carrying case, battery, coupling gel and instructions. Extra headset is available for $38.50.

When your patients ask QUESTIONS be prepared with the ANSWERS.

As you know, the attitudes of today's women are changing dramatically. Women want to understand more about their bodies, they want to know the reasons behind the ob/gyn treatment they receive, and they trust you enough to ask. Mosby references will not only help you brush up on the answers — they'll bring you current concepts and techniques for treating the problems you encounter every day. See for yourself ...

New 6th Edition

OBSTETRICS AND GYNECOLOGY

For a truly integrated approach to the study of obstetrics and gynecology, turn to this new reference. Emphasizing treatment of the total woman, the book's organization follows the normal life cycle of women — starting from birth and going through puberty maternity, climacteric and senescence.

As in previous editions, this edition offers the ideal alternative to either a synopsis presentation or a comprehensive reference. In discussing methods of diagnosis and treatment, you'll find emphasis on methods that can be used by the nonspecialist, but conditions requiring more specialized training are also included, in abbreviated form.

Updated to reflect current thought, the book:

- presents both obstetric and gynecologic information in one single source;
- provides sound advice on various methods of contraception and discusses the advantages and disadvantages of each;
- presents various changes in physiologic functions as a result of aging;
- identifies core material by use of a different type size.

Be among the first to take advantage of this excellent resource — reserve your copy today!

By J. Robert Willson, M.D. and Elsie Reid Carrington, M.D. May, 1979. Approx. 736 pp., 609 illus. **About $26.50.**

New 10th Edition

SYNOPSIS OF OBSTETRICS

Like its predecessors, this new edition presents the basic principles of obstetrics, emphasizing the management of the normal pregnancy, and discusses most common complications of labor, delivery, and the puerperium period. Included among the new features is an unprecedented stress placed on the importance of fetal monitoring. Examine some of the other key features of this book, and you'll be impressed by its timeliness:

- Two totally new chapters: "Prenatal Assessment of Fetal Maturity and Intrauterine Status," and "Prematurity, Dysmaturity and Postmaturity";
- A totally rewritten chapter on abortion, stressing different techniques and the need for counselling regarding alternatives;
- An examination of the latest methods of feta assessment;
- A thorough look at sterilization and contraception techniques, including the newer methods for intra-coital, pre-coital, and post-coital contraception;
- A convenient 5" x 7½" size.

You won't find a better reference/review of obstetrics in such a concise format. Order your copy today!

By Eugene C. Sandberg, M.D. October, 1978. 656 pp., 287 illus. **Price, $14.95.**

CURRENT DEVELOPMENTS IN PERINATOLOGY: The Fetus, Placenta, and Newborn

Why do you read The American Journal of Obstetrics and Gynecology? Because it keeps you up-to date? Because it allows you to benefit from the combined experience of leaders in your field?

Whatever your reasons, they'll also lead you to this contemporary volume. A compilation of articles from The American Journal of Obstetrics and Gynecology, it shares the insights of authorities in the field — wherever necessary, the articles have been updated by the original authors. Each of the five sections is preceded by an introduction which correlates material to follow. The first three sections examine antenatal fetal assessment — congenital defects, hormonal aspects, pulmonary aspects, and growth and development. The last two sections discuss the placenta and various factors affecting both fetus and newborn.

You look to this excellent journal for current information relevant to your needs. Why not look to this unique reference for an expanded and updated version of some of the journal's outstanding articles you've found helpful in the recent past? For a personal evaluation, simply fill out the coupon and send for your copy.

Edited by Frederick P. Zuspan, M.D. 1977. 630 pp., 142 illus. **Price, $42.50.**

A New Book

MICROSURGICAL COMPOSITE TISSUE TRANSPLANTATION

In this new extraordinary reference, internationally- distinguished authorities combine their vast years of experience to offer you a well-balanced approach to the basic science, experimental, and clinical aspects of this subject. Throughout, you'll benefit from both the surgeon's extremely practical approach, emphasizing technique, and the researcher's stress on physiological aspects — the basis of successful technique.

The first of seven comprehensive sections details the latest basic science concepts. Two subsequent sections investigate current clinical problems in the laboratory model, and examine anatomy of donor tissue and various factors necessary for successful transfer to distant sites. The remaining four sections explore all facets of this new reconstruction method, frequently comparing it with older, existing methods. Contributors emphasize regional reconstruction of recipient sites in the head and neck, thorax and breast, and extremities.

This is an exceptional opportunity to refine both your skills and understanding with the help of such international experts as Kitaro Ohmori, Ian Jackson, and Harry Buncke, Jr. Why not order your copy now, while you have the time?

Edited by Donald Serafin, M.D. and Harry J. Buncke, Jr., M.D.; with 63 contributors. December, 1978. 812 pp., 982 illus. **Price, $52.50.**

New 2nd Edition

HUMAN SEXUALITY IN HEALTH AND ILLNESS

The first edition of this reference was very well-received — and now, you'll find the expanded second edition (30% larger) to be even better than before! In a highly readable, non-moralizing style, the author and seven contributors again deal with the topic of human sexuality in illness as well as in health. Three major units provide a holistic overview of the subject; discuss it from assessment, prevention, and restorative viewpoints; and focus on its clinical aspects.

You'll appreciate four completely new chapters:

- "Assessment of Sexual Health"
- "Roles for Professional Nurses in the Delivery of Sexual Health Care"
- "Sexuality, Fertility, and Infertility"
- "Sexuality and Mental Health"

You'll also find significant additions on stress and on nursing assessment, diagnosis, and intervention of problems in human sexuality. If you missed the first edition of this outstanding reference, be sure to catch the second. And if you already have the first edition, remember — the new edition is more comprehensive than ever! So send in the coupon now!

By Nancy Fugate Woods, R.N., M.N., Ph.D.; with 7 contributors. March, 1979. 412 pp., 11 illus. **Price, $9.95.**

New! Available for the first time

The ten-year **cumulative author and subject index** to volumes 100-129 (1968-1977) of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY is now available for your journal collection. It is a complete and comprehensive reference guide to over 28,000 pages of authoritative articles published in the Journal during the past ten years.

The world-renowned "Gray Journal" is the oldest specialty journal devoted to obstetrics and gynecology.

Now these influential papers, appearing between 1968-1977, have been cross-referenced to include over 23,100 subject entries. Each entry lists the complete article title, author(s), volume, page, and year of publication.

The author index lists more than 13,850 contributors from this period, along with respective article title, author-to-author referral, volume, page, and publication date.

The 479-page index is handsomely presented in a rust and gold cloth-cover volume. It is a must for every library concerned with obstetrics and gynecology. Send for your copy of this valuable reference today!

479 pages, 8¼" × 11", price $28.75

CURRENT DEVELOPMENTS

Ultrasound in the diagnosis of congenital anomalies

JOHN C. HOBBINS, M.D.
PETER A. T. GRANNUM, M.D.
RICHARD L. BERKOWITZ, M.D.
ROSAMUND SILVERMAN
MAURICE J. MAHONEY, M.D.
New Haven, Connecticut

With high-resolution ultrasound equipment, it is now possible to diagnose certain fetal anomalies in the third trimester and in some cases before the twentieth week of gestation. During a 27 month period 2,548 ultrasound scans were performed in high-risk patients. An anomaly was diagnosed in 10 of 122 second-trimester patients who were at risk for recurrent fetal defects. Fetal deformity was also found in 26 third-trimester patients. Of the 2.8% of patients found to have polyhydramnios 18% were associated with various types of anomaly. With ultrasound it was possible to examine internal fetal anatomy and to identify abnormalities of the fetal cranium, spine, chest, abdomen, and limbs. These anomalies are reviewed here in detail. Based on ultrasonically derived information, second-trimester patients can be offered information concerning the status of their fetuses at risk genetically and physicians can better manage third-trimester patients with diagnosed fetal deformities. (AM. J. OBSTET. GYNECOL. 134:331, 1979.)

WITH THE IMPROVED sophistication of high-resolution gray-scale ultrasound equipment, it has become possible to better delineate fetal anatomy. This has enabled the ultrasonographer to identify some fetal anomalies which have previously eluded diagnosis. As a result, second-trimester patients who have already been delivered of infants with inherited defects can often be offered diagnostic information early enough to allow them the option of terminating the pregnancy. In the third trimester, pregnancies complicated by fetal anomaly are not terminated unless the condition is incompatible with extrauterine survival. However, ultrasonically derived information may be critical to the patient's obstetric management as well as the immediate care of the newborn infant. For these reasons, it is important that those responsible for the care of patients at risk for fetal anomalies are aware of the diagnostic potential of ultrasound, its advantages, and its limitations.

This report reviews our experience in the diagnosis of congenital anomalies in utero with ultrasound during the period from June, 1976, through August, 1978. Scanning was done in a total of 2,548 patients who either had various complications of pregnancy (Table I) or were at risk for fetal anomalies (Table II). Many of the patients studied were referred from locations outside our catchment area because of a high-risk pregnancy or suspicious findings at the referring institution.

Nonspecific ultrasonic findings associated with fetal anomalies

Abnormalities of amniotic fluid volume. Many fetal anomalies are associated with either excessive or diminished amounts of amniotic fluid. The volume of this fluid increases linearly until the thirty-eighth week

Table I. Diagnosis of congenital anomalies made in the third trimester in patients studied during a 27 month period

Anomaly	*No.*
Hydrocephalus	5
Anencephaly	7
Intrathoracic cyst (enteric cyst)	1
Diaphragmatic hernia	1
Duodenal atresia	2
Multicystic kidney disease	2
Ureteral obstruction with cystic dysplastic kidney	1
Omphalocele	1
Thanatophoric dysplasia	1
Miscellaneous multiple anomalies	5
Total	26

Table II. Diagnosis of congenital anomalies in second trimester in patients genetically at risk for fetal deformity*

	Pregnancies examined (No.)	*Positive diagnoses (No.)*
Hydrocephalus	17	3
Neural tube defects (total of 82):		
Anencephaly in previous pregnancy	37	0
Spina bifida in previous pregnancy	41	1
Meningomyelocele in previous pregnancy	4	0
Polycystic kidney disease	4	2
Renal agenesis	2	0
Short limbed dysplasia	9	2
Fanconi's anemia	1	0
Roberts syndrome	4	2
Asphyxiant thoracic dysplasia	2	0
Thoracochondrodystrophy	1	0
Total	122	10

*Other anomalies described in text were not in those patients at risk genetically.

of gestation, at which time a mean volume of 1,000 cc is present.[2] After 38 weeks, the quantity of fluid diminishes progressively to about 250 cc at 43 weeks.[2] Well-defined limits of normalcy, however, have not been described. Precise determination of amniotic fluid volume is difficult and the only ultrasonic method reported, which derives this measurement by cross-sectional pelvimetry,[26] is beyond the constraints of most ultrasound laboratories. Calculation of total intrauterine volume (TIUV)[14] permits semiquantitative determination of this variable in the serial monitoring of a pregnancy. Although an abnormal TIUV is defined as being outside 95% confidence limits for a given gestational age, many pregnancies complicated by fetal anomaly are associated with lesser degrees of deviation from the mean.

Oligohydramnios. Oligohydramnios can be ultrasonically appreciated by noting a paucity of fluid in the area of the fetal arms and legs. This produces an impression of crowding (Fig. 1). The fetal kidney plays an important role in the formation of amniotic fluid. Oligohydramnios, therefore, strongly suggests fetal renal impairment in a pregnancy at risk for kidney abnormalities. This is particularly true when the reduction in amniotic fluid volume is noted before the twenty-eighth week of gestation. After this time, nonanomalous situations such as intrauterine growth retardation (IUGR), premature rupture of membranes (PROM), or postterm pregnancy may be responsible for oligohydramnios. The above conditions were responsible for oligohydramnios found in 7% of the patients studied.

Polyhydramnios. Amniotic fluid is in part cleared from the uterine cavity by fetal swallowing,[13] and conditions which compromise this function often result in polyhydramnios (Fig. 2). These conditions would include central nervous system abnormalities such as anencephaly and meningomyelocele. Obstruction to the fetal gastrointestinal tract proximal to the ileum is also consistently associated with polyhydramnios.[33] Since intrathoracic cysts and diaphragmatic hernias can be associated with polyhydramnios, it is likely that another cause of polyhydramnios is extrinsic pressure on the upper gastrointestinal tract.

Polyhydramnios is often noted in complications of pregnancy apart from fetal anomalies, such as Rh disease or diabetes. In many circumstances polyhydramnios occurs for no apparent reason, and in some cases the condition is not seen on repeat scan. During the study period, ultrasonically appreciated relative hydramnios (persisting on repeat scans) was diagnosed in 2.8% of pregnancies and anomalies were noted in 18% of these cases. This is in accord with a previous study suggesting a 20% chance of anomaly in polyhydramnios.[28] It is of interest that in an additional 22 cases polyhydramnios was diagnosed but was not evident on repeat examination.

Ascites. Ascites can be detected on transverse scanning by noting an echo-spared area surrounding the intraperitoneal contents (Fig. 3). This condition can be differentiated from a large intra-abdominal cyst by the uniformity of fluid accumulation in all quadrants of the abdomen. Fetal ascites occurs in a variety of conditions, such as urinary tract obstruction, chylous ascites, "prune belly" syndrome, and other multiple anomaly syndromes.[12] Although the exact etiology of fetal ascites is unknown, it has been postulated that the intra-

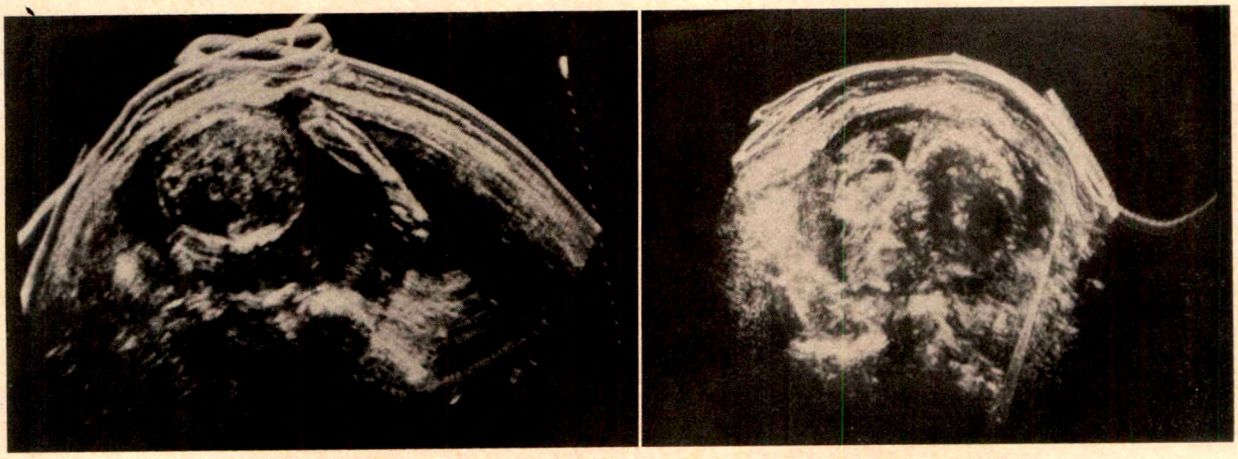

Fig. 1. Oligohydramnios. These transverse scans were obtained in two pregnancies of the same gestational age. There is marked crowding of the fetal small parts on the scan to the right. The uterine diameters are significantly smaller.

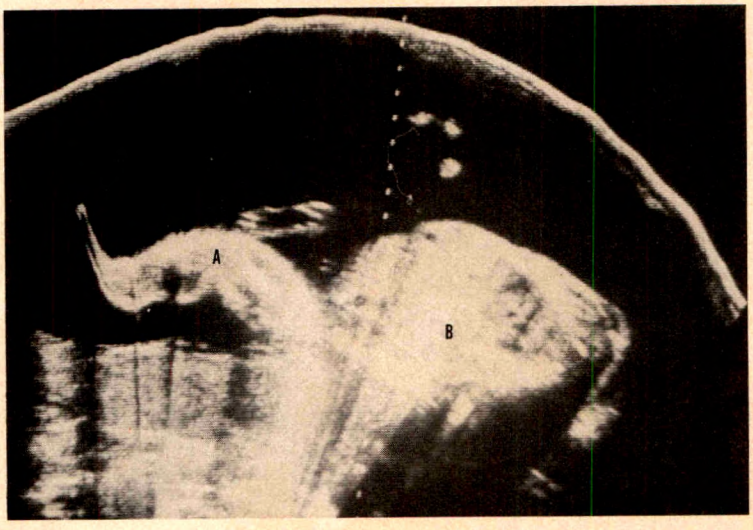

Fig. 2. Polyhydramnios. The ample black area represents excessive amniotic fluid. *A:* Leg; *B:* body.

peritoneal fluid accumulates as a result of heart failure, obstructed venous return, hypoproteinuria, or a combination of these. When fetal ascites is seen, the prognosis is ominous, although we are aware of two rare cases where infants have lived when the ascites was an isolated finding. During the study period, all five anomalous fetuses with ascites died either before delivery or within a few days following birth. One fetus, however, was delivered at 34 weeks after about 500 cc of ascitic fluid was removed from the fetal abdomen. The infant died of respiratory distress, and at autopsy the only abnormality found was fibrous bands in the peritoneal cavity.

Hydrops. It has been assumed that the generalized edema seen in fetal hydrops is secondary to cardiac failure. Validation of this concept, however, awaits studies of fetal cardiac function. Hydrops is manifested by abnormal thickening of the placenta (more than 5 cm) and a preponderance of low-level echoes within the placental substance. Subcutaneous edema is identified by increase in thickness of the scalp and abdominal wall. The liver is often enlarged, and ascites is a consistent feature. Although fetal hydrops is noted in severe erythroblastosis, generalized edema can also result from nonimmune causes. For instance, it was possible in one patient to diagnose alpha thalassemia at 22 weeks' gestation by the finding of gross placental hydrops. Amniotic fluid and fetal blood studies con-

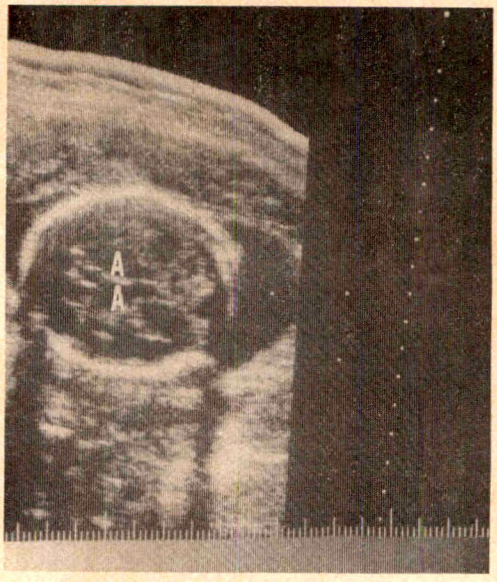

Fig. 4B. Normal lateral ventricles *(A)* at 19 weeks.

firmed the diagnosis. Fetal hydrops, whatever the cause, is associated with a grave prognosis.

Specific fetal areas

Cranium. Approximately 10% of major fetal anomalies involve the head and spine. Although abnormalities of the fetal cranium have been reported with ultrasound in the third trimester,[8, 11, 20, 25] most of these deformities can be identified in the second trimester.

Hydrocephalus. Recent investigation[3] has indicated that the lateral ventricles become abnormally dilated in hydrocephalus before there is a change in the outer skull outline. Therefore, scans in early pregnancy may reveal a normal biparietal diameter (BPD) and head circumference but show an extension of the lateral ventricles past a point which is midway between the falx and the outer skull outline (Fig. 4A). Under normal circumstances, the ventricles should not occupy this

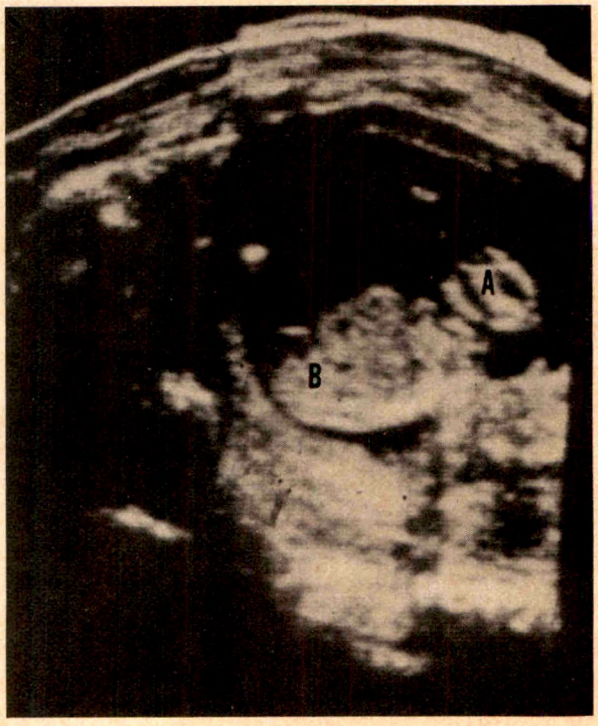

Fig. 5. Anencephaly. Facial structures are seen in this 15 week anencephalic fetus. The calvarium is absent. *A:* Face; *B:* body.

large an area after the seventeenth week of gestation (Fig. 4B). Failure to find dilated ventricles at this time does not exclude the development of hydrocephalus later in gestation, but preliminary experience suggests that this is not common.

In this series, scanning was done in the second trimester in eight patients who had been delivered of infants with communicating hydrocephalus (the most common form of the condition). In one of these cases, dilated lateral ventricles were noted. The pregnancy was terminated and the diagnosis confirmed at autopsy. In two other second-trimester patients not at recognized risk for fetal hydrocephalus, dilation of the lateral ventricles was diagnosed. One pregnancy was terminated (at which time the diagnosis was confirmed) and the other continued. In the latter case the BPD enlarged appropriately for gestation until the thirty-third week, after which the BPD increased by 2.7 cm in 4 weeks (mean normal growth, 1.5 cm). The infant was delivered at 37 weeks and lived only a few hours. Autopsy confirmed the diagnosis of hydrocephalus. In all of these cases of hydrocephalus, the BPDs were within one standard deviation of the mean for gestation before the twenty-fourth week.

Some forms of hydrocephalus have a higher recurrence risk than the empiric 1% to 4%.[29, 31] One of these

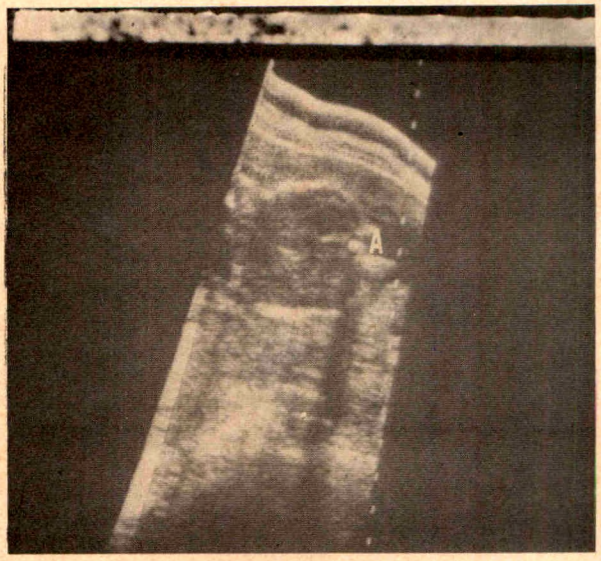

Fig. 6. Spina bifida. Defect in spinal column. Transverse scan at level of the first lumbar vertebra *(A)*.

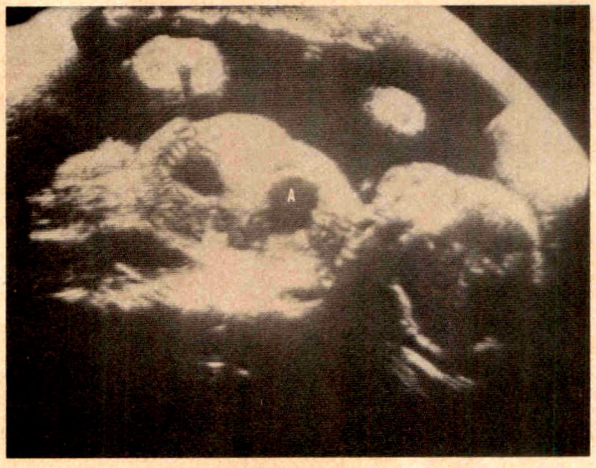

Fig. 7. Diaphragmatic hernia. This sagittal scan reveals an intrathoracic echo-spared area *(A)* adjacent to the heart, representing herniated abdominal contents.

is aqueductal stenosis, a block between the third and fourth ventricles. This condition may be secondary to hemorrhagic or inflammatory processes in the brain or may occur as an X-linked trait. The former etiologies probably represent acquired, nongenetic disease whereas the latter predicts familial recurrence in male offspring. X-linked aqueductal stenosis, inherited from the mother, has a 50% recurrence in male offspring and essentially no occurrence in female offspring. Accurate estimates of the genetic proportion of congenital aqueductal stenosis do not exist, but one writer[10] suggested that 2% of all cases of uncomplicated hydrocephalus have X-linked aqueductal stenosis. If

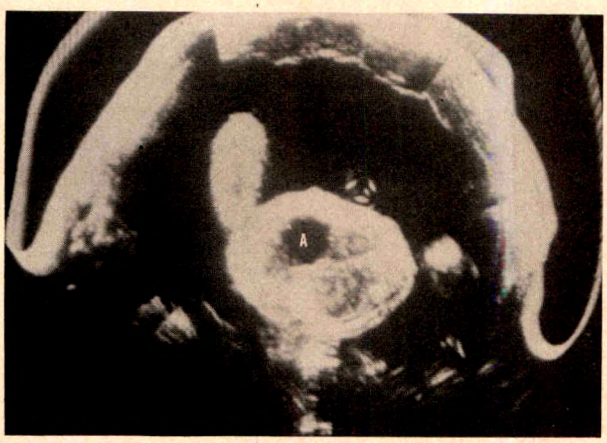

Fig. 8. Diaphragmatic hernia. A transverse scan at the level of the diaphragm demonstrates the defect *(A)*. (From Touloukian, R. J.: Intestinal atresia, Clin. Perinatol. 5:3, 1978, published by W. B. Saunders Co.)

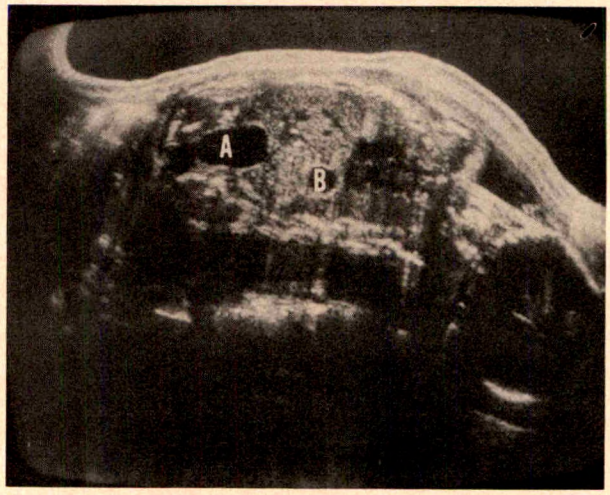

Fig. 9. Sagittal scan of normal fetal bladder *(A)* and stomach *(B)*.

aqueductal stenosis has been diagnosed in a previous male offspring, a fetal karyotype should be obtained. Although the index of suspicion is much greater in a male fetus, thorough sonographic evaluation of the fetal cranium should be performed in all fetuses unless there is clear genetic evidence for the X-linked variety.

A patient who was delivered of two male infants with hydrocephalus, the last of whom was diagnosed as having aqueductal stenosis, had an amniocentesis at 16 weeks which revealed a male fetus. Scans at 20 weeks suggested dilated lateral ventricles, and repeat examination at 23 weeks confirmed this impression. The BPD was within normal limits. Hydrocephalus with marked cortical thinning was found in the abortus.

In the third trimester the diagnosis of hydrocephalus is not difficult to make since the head circumference is often very large. In these cases, information obtained from ultrasound may be extremely useful in the patient's obstetric management. Because of improvements in shunting techniques, neurosurgeons can now offer a life of reasonable quality to some infants with hydrocephalus. Therefore, it is important that obstetricians confronted with a diagnosis of fetal hydrocephalus develop criteria which will aid them in choosing the route of delivery. With ultrasound it is possible to obtain BPD and head circumference measurements, to detect intracranial asymmetry with attendant deviation of the falx (the ultrasonic midline), and to measure the thickness of the cortex. There is extremely poor infant survival when the fetal head circumference measurement exceeds 50 cm. Also, a shift of the midline is usually associated with porencephalia which has an ominous prognosis. If the thickness of the cerebral cortex is less than 1 cm, this correlates with poor neurological potential. The ultrasonic diagnosis of hydranencephaly (absence of the cerebral cortex) has been reported.[20] This condition is not associated with infant survival; therefore, the prenatal diagnosis of this condition would be extremely valuable in the obstetric management of the patient. Since spinal defects are also noted in some cases of hydrocephalus and because large defects have a guarded prognosis, a careful spinal scan should also be performed. Vaginal delivery with decompression of the fetal head by aspiration is relegated only to those cases where the prognosis is hopeless. However, if there is a chance of survival with reasonable function based on the above information, then cesarean section should be performed once there is evidence of pulmonary maturity in the fetus.

During the study period, hydrocephalus was accurately diagnosed in five third-trimester patients. Cesarean section was performed in all five patients, including a woman who declined vaginal delivery despite significant porencephalia in the fetus, which was later confirmed in the infant by computerized tomography.

One misdiagnosis of hydrocephalus was made in an additional patient. She was referred from another hospital where the diagnosis of fetal hydrocephalus had been made ultrasonically. The fetal head was larger than average (BPD of 9.6 cm at 35 weeks compared with a mean and standard deviation of 8.6 ± 0.4 cm); the lateral ventricles seemed dilated, and there appeared to be a shift of the midline structures. Based on these findings, the infant was delivered by cesarean section at 37 weeks. Although the infant's head circumference was in the ninety-eighth percentile, he appeared to be neurologically normal. Computerized tomography was not performed until 9 weeks of age, at

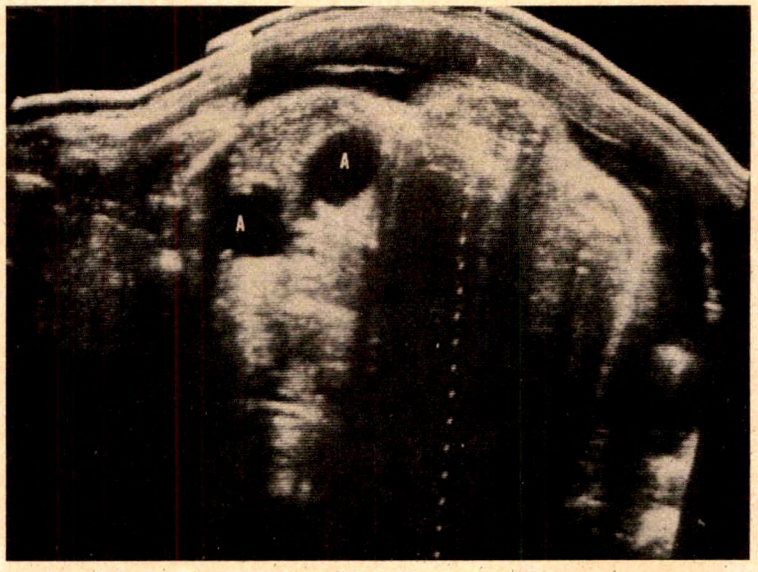

Fig. 10. Duodenal atresia. This 32 week fetus had a classic "double bubble" sign composed of dilated stomach and duodenum seen in duodenal atresia. *A:* Echo-spared areas.

which time there was no evidence of hydrocephalus.

There are structures in the fetal head such as the sylvian fissure which may be mistaken for the outer margin of the lateral ventricle. The distinction between structures, however, should be appreciated by scanning through the fetal head in many planes. Although many more patients will require ultrasonic evaluation before one can appreciate the true rate of false negative and positive diagnoses of hydrocephalus, it is hoped that the incidence of misdiagnoses will be negligible in the hands of a cautious and experienced ultrasonographer.

Neural tube defects.

ANENCEPHALY. In most cases anencephaly is not difficult to diagnose. With instruments of good resolution, it is possible to discern a poorly formed cranium by the fifteenth week of gestation. In later gestation, however, the cranial pole is often driven deep into the pelvis where it is difficult to evaluate ultrasonically. Even in normal pregnancy, an engaged cranium is occasionally too deep in the pelvis for ultrasonic visualization and anencephaly is erroneously suspected. In these cases pelvic examination and x-ray studies should be used for further evaluation.

During the study period, 82 patients at risk for neural tube defects, of whom 37 had previously been delivered of anencephalic fetuses, were examined in the second trimester. Well-formed craniums were found in all of these cases. In two other second-trimester patients who were not at risk, anencephaly was diagnosed at 15 weeks (Fig. 5) and 22 weeks when scans were performed to establish gestational age. The condition was also diagnosed in seven third-trimester patients referred because of clinically apparent hydramnios.

Spine. The efficacy of screening with maternal serum alpha-fetoprotein (AFP) determinations for neural tube defects is no longer questioned. Screening programs generate 2% to 3% of pregnancies which require further evaluation by ultrasound and amniocentesis.[34] In contrast to anencephaly, spina bifida is difficult to diagnose with ultrasound and requires significant operator experience. With large defects, splaying of the fetal spine can be noted in sagittal scans. However, if a defect is not seen on sagittal examination the diagnosis cannot be excluded until a series of carefully spaced transverse scans fails to identify an incompletely closed spinal segment.[3, 5, 17] Even with a detailed examination, the sacral spine often cannot be completely evaluated because of poorly defined landmarks in that area.
